PREFACE

This Handbook is designed as a reference on poultry diseases and conditions that occur in Africa. It focuses on common diseases and conditions and includes practical information on diagnosis and treatment.

The first section of the handbook provides information on the causes of disease, categories of disease, clinical signs, and necropsy. In the second section, diseases are arranged alphabetically and individually described. Coverage for each infectious disease generally includes these subtopics:

- Name (including common names)
- Clinical signs and lesions
- Differential diagnoses
- Cause, transmission, epidemiology
- Diagnosis
- Prevention
- Treatment
- Recovery

To diagnose poultry diseases, use the Poultry Disease Diagnosis Decision Tree in Appendix A of this Handbook to identify the possible diseases or conditions based on clinical signs and lesions. Then read the brief descriptions in the Disease charts beginning on page 8. For more detailed information on signs, cause, transmission, differential diagnosis, and guidance on prevention, treatment, and recovery, find the descriptions of the suspected diseases in the Poultry Diseases section beginning on page 14.

Editorial Team:

Dr. Carol J. Cardona
Sandra S. Shanks
FOREWORD

When Avian Influenza (AI) gained world attention in 2005 following a series of outbreaks of the H5N1 virus in China, Central Asia, the Middle East, Europe, and Africa, the Global Livestock Collaborative Research Support Program (GL-CRSP) through the University of California Davis School of Veterinary Medicine began to rapidly develop a project to train trainers for the monitoring, detection and response to AI in developing countries. The project, Avian Flu School (AFS), was highly successful, producing an effective curriculum and teaching protocol that was conducted in more than 12 countries and reaching over 5,700 people including veterinarians, agricultural extension agents, and village leaders worldwide. Through this training process, the AFS team became increasingly aware of the constraints and opportunities for improving rural poultry production in Africa, specifically through the vaccination and control of Newcastle disease (ND), one of the major sources of poultry mortality at the village level in developing countries. The AFS focus on overall poultry health led to another GL-CRSP project implemented by AFS, where the team assessed the impact of a ND mass vaccination program in free-ranging chicken flocks on the welfare and food security of villagers in Tanzania.¹

The intimate involvement of AFS in village-level poultry production has emphasized the importance of poultry disease management on the welfare of people in developing countries. Poultry are a primary source of animal food for millions of the world’s most poor, and increased poultry and animal source food intake can significantly enhance livelihoods, especially among children. A previous intervention study by the GL-CRSP Child Nutrition Project (CNP) in Kenya has demonstrated the positive impact of the consumption of animal source foods on child cognitive and physical development², along with its implications for national development.³ In addition, the GL-CRSP Enhancing Child Nutrition through Animal Source Food Management (ENAM) project in Ghana has shown that poultry production, in conjunction with microfinance and nutritional education, can be highly profitable for women while improving the nutrition of their children.⁴ However, despite the emergence of poultry as a potential resource for economic gain and improved nutrition for the poor, AFS research has identified common poultry diseases as a major impediment to realizing such gains.

One of the primary constraints to effective disease control has been the lack of diagnostic capacity, especially for poultry at the village level. Village veterinarians and extension agents have traditionally relied upon personal training (often under very different contexts from the village setting) for poultry disease diagnostics, as there was no manual specific to poultry diseases in Africa. Disease management and treatments under this approach is often improperly targeted, and the resulting

¹ To monitor effectively for AI, control of Newcastle disease is critical to detection since the outward symptoms are similar.
⁴ More information on the ENAM project can be found at: http://glcrsp.ucdavis.edu.
poor performance of treatments not only reduces production, but also diminishes faith in veterinary services, further invalidating recommended management and treatment options.

This manual, the “Poultry Disease Handbook for Africa,” was developed to address this void. This handbook provides practical information on disease diagnostics, control and prevention for veterinarians and animal health professionals, and provides the tools to effectively diagnose, treat and manage disease in the village context. The Handbook is based on the synthesis of research and information from a wide variety of sources by the authors, and is tailored to the African environment based on their insight and experience.

Apart from its critical importance to the African poultry and animal health communities, the development of this handbook also represents an important step in the role for US universities in development. As envisaged under Title XII of the US Foreign Assistance Act, Collaborative Research Support Programs (CRSPs) are intended to draw upon the scientific capacity of US universities to address poverty and food security challenges in developing countries. The development of this handbook is a perfect example of how efficiently and effectively the expertise of a university can be used as a tool to address the goals of Title XII. The Handbook is also a practical and fundamental step in facilitating the implementation of knowledge gained through the Child Nutrition and ENAM Projects to enhance rural livelihoods and improve child cognitive and physical development. In the end, children are the future of all social and economic gains.

Montague W. Demment
Program Director
Global Livestock CRSP
CAUSES OF DISEASE

IMPORTANT POINT: IF A BIRD IS SHOWING SIGNS OF DISEASE, THEN THERE IS A REASON.

Diseases can be caused by things you can see and things that you can't, including bacteria, viruses, fungi, parasites, and poisons. An incomplete diet may also cause disease.

1. **Bacterial** diseases can be treated with antibiotics.
2. **Viral** diseases cannot be treated with antibiotics. Vaccines can be effective for preventing some viral diseases.
3. **Fungi** may cause illness either by growing in the birds or by producing poisons. There are no treatments for fungal diseases, but they can be controlled by cleaning the environment.
4. **Parasites** can irritate and annoy birds, and some can transmit bacteria and viruses. Parasites are categorized as either internal or external, depending on whether they live in or on the bird.
   - **External parasites** generally bite and irritate birds, but can also cause blood loss and transmit diseases. *Mites, lice, and ticks* are all external parasites. *Flies, fleas, beetles,* and *mosquitoes,* although they live both on and off the bird, can transmit diseases like fowl pox between birds, and they can serve as a source of poisons.
   - **Internal parasites** can be very small (like coccidia) or very large (like most worms). There are treatments and vaccines for some internal parasites.
5. **Poisons** like botulinum and aflatoxin are produced by living organisms (fungi and bacteria). Poisons that are made by humans, like pesticides or disinfectants, can also cause clinical signs in poultry if they eat or drink them.
6. **Nutritional deficiencies** can result in signs of illness and death, especially in young birds. Once the deficit has been identified and corrected, the birds will often make a rapid recovery.
7. **Environmental conditions,** especially heat, can kill large numbers of birds and are among the key causes that should be considered when there is high mortality. Heat loss is more common in confined birds than those that are free-ranging.
8. **Predation** usually results in the loss of a few birds rather than whole flocks.
CATEGORIES OF DISEASE IN POULTRY

Bird diseases and conditions can be divided into three categories.

Category 1 Diseases:
1. Death in the flock is very high – often up to 100%.
2. Multiple organ systems (respiratory, digestive, nervous, reproductive, etc.) are affected by these diseases.
3. Trade restrictions may be associated with these diseases; quarantines and notification of animal health authorities may be required.
4. Prevention through vaccination and biosecurity are the only options. Treatment of active disease is ineffective. Stamping out flocks may be the only option for eradicating the disease once birds are infected.

Category 2 Diseases:
1. Mortality is lower than in Category 1 disease and/or treatment is possible.
2. Only one or a few organ systems are involved.
3. These diseases limit how much income a community can earn from poultry flocks; they result in the death of some birds, decreased egg production, and/or lower feed conversion rates.
4. There are medications, vaccinations, and other treatments available for these diseases.

Category 3 Diseases:
1. These are conditions rather than diseases, and are not caused by organisms that are spread between birds.
2. Depending on the cause, they may affect multiple organ systems.
3. They are environmental in origin, and control is achieved mostly through providing adequate housing, diet, and sanitation.
4. Medication may be available for some conditions in this category.
Sick birds show clinical signs.

Clinical signs are caused when a disease or condition affects all or part of a bird's body.

**IMPORTANT POINT: THE PART OF THE BIRD THAT IS AFFECTED ON THE INSIDE WILL DETERMINE THE CLINICAL SIGNS THE BIRD SHOWS ON THE OUTSIDE.**

Many clinical signs are specific to the organ system that is affected on the inside of the bird. The parts of the bird that work together so that the bird can function comprise an organ system. For example, the lungs, nose, and trachea are part of the respiratory system, which together keep the bird breathing.

*Table 1. Organ systems, their functions and what clinical signs appear.*
Example of an organ system: The digestive system includes all of the parts of the bird that are involved in eating, drinking and digesting. The function of the digestive system is to provide fuel for all of the other systems. *Illustration by Ruben Byrd, Mongrel designs (mongreldesigns.com).*
NECROPSY OF BIRDS

1. Review the clinical history and consider what the likely diagnosis is.

2. Examine the outside of the bird. Then, if the bird is still alive, observe how the bird acts. Check for external parasites.

3. Humanely euthanize the bird. (See Handout Y: “Humane Euthanasia of Individual Birds”)

4. Moisten the feathers with water containing a small amount of soap.

5. With scissors, cut through one corner of the mouth and open it so that the oral cavity can be examined.

6. Continue the cut down the neck of the bird from the mouth to the chest, through the skin only. Examine the size of the thymus, if present.

7. Make an incision down the esophagus from the mouth to the crop. Examine the upper digestive tract.

8. Make an incision down the trachea from the mouth to the chest. Examine the trachea.

9. With heavy scissors, cut across the beak just in front of the eyes. Examine the nasal cavities.

10. Using a scalpel or one side of a small scissors, cut into each infraorbital sinus, just below the eye. Examine the color and look for mucous or other material.

11. Pull the leg bones out of the hip joints. Bend the legs backwards, towards the back of the bird.

12. Cut the skin on the inside of each thigh from the hip to the stifle joint. Pull the skin back so you can see the thigh muscles.

13. Make another cut through the skin of the abdomen that connects the two cuts on the thighs. Pull the breast skin up and the abdominal skin down so that the muscles of the midsection of the bird are exposed.

14. Using scissors, make a cut in the abdominal body wall that follows the bottom edge of the rib cage. Be careful not to puncture the intestines.

15. Continue this cut through the ribs on either side. Cut through the bones without damaging the organs underneath. Be sure to cut through the strong coracoid bones at the top of the rib cage.

16. Now that the ribs have been cut, lift the breast. Observe the air sacs as you do this, because they will be disrupted in the process.

17. All the organs should now be exposed. Look at them while they lie in place, noting size and color.

18. Examine the pancreas.
19. Cut across the esophagus just above the proventriculus. Pull downward so that the digestive tract comes away from the bird and can be examined in detail.

20. Using scissors, cut length-wise down the digestive tract to examine the inside. You may need heavy scissors or a scalpel to get through the tough muscle of the ventriculus. Examine for parasites, noting the gut contents and their consistency.

21. Remove and examine the liver and spleen.

22. Examine the reproductive organs. In the female, remove the ovary and oviduct. Note if the bird has an active or inactive ovary. Cut the oviduct length-wise to look at the inside.

23. Remove and examine the heart.

24. Examine the lungs. Remove them by freeing them from their attachment to the ribs. Note color and consistency.

25. Look at the sciatic nerves in each thigh. You may need to remove the leg muscles to find them.

26. With a sharp blade, open each knee (tibiotarsal) joint and examine the articular fluid for color and consistency.

27. With a sharp blade, split one leg bone length-wise to expose the bone marrow. Note its color.

28. To examine the brain, remove the head from the body and remove the skin. With strong scissors, carefully chip and peel off the top of the skull to expose the brain. Be careful not damage the brain. Observe for lesions.

**Reproductive:** Decreased egg numbers and hatching, increased blood spots in eggs. | Supplement vitamins in the water or feed, add antioxidants to feed, rotate feed |
POULTRY DISEASES
(Listed Alphabetically)

Aspergillosis

Other names: brooder pneumonia, mycotic pneumonia, fungal pneumonia, Aspergillus, pneumomycosis, bronchomycosis, and colloquialisms ('asper' and 'airsac'). When the source of the disease is the hatchery, the disease is called brooder pneumonia. In older birds, the disease is called aspergillosis.

Clinical signs and lesions: Aspergillosis occurs as an acute disease of young birds and a chronic disease in mature birds. Young birds have trouble breathing and gasp for air. Characteristically, there are no rales or respiratory sounds associated with aspergillosis. Feed consumption decreases. Occasionally there is associated paralysis or convulsions caused by the fungal toxin. Mortality in young birds averages 5-20%, but may be as high as 50%. Mature birds also show respiratory distress, reduced feed consumption, and may have a bluish and darkened skin color (cyanosis). Nervous disorders, such as twisted necks, may occur in a few birds. Mortality in mature birds is usually less than 5%.

Lesions typically consist of friable grey or yellow to greenish nodules or plaques, and fibrino-caseous deposition in air sacs, lungs, and trachea. Similar lesions can occur in other organs such as the liver, peritoneal cavity and other sites. Lesions in the brain consist of solitary abscesses. Mycelial growth with spores may be apparent in air sacs, bronchi, and sites where oxygen content is sufficient for sporulation.

Differential diagnosis: Avian aspergillosis signs are nonspecific and depend on the system involved. The disease may produce similar signs to Dactylariosis. Pulmonary aspergillosis is usually differentiated from other avian respiratory diseases by the granulomatous lesions at necropsy, but needs to be differentiated from other mycoses and mycobacteriosis. However, exudative fibrinous or caseous air-sacculitis and pneumonia need to be differentiated from mycoplasmosis, colibacillosis, fowl cholera, and chlamydiosis. Aspergillosis affecting the skin needs to be differentiated from ectoparasitic infestations, smothering, cannibalism, and molting or other causes of feather loss in birds.

Cause, transmission, and epidemiology: Aspergillosis fungi are ubiquitous in the environment and grow well at room temperature and higher. All birds (domestic poultry, pigeons, canaries, and zoo bird species), other animals, humans, and plants are susceptible. All litter and nest materials (peat moss, peanut hulls, sawdust, peat, bark, and straw) are can become contaminated with Aspergillus, which grows rapidly where there is moisture present. Feed and water should be suspect when attempting to identify the source of contamination. The fungus can penetrate egg shells and infect embryos. Infection is usually caused by inhalation of large amounts of fungal spores, exposure to contaminated eggs during incubation, and dust from the poultry shelters, coops, and areas where birds aggregate.

In smallholder farms in Africa, aspergillosis occurs in free-range poultry during the planting and the harvesting periods. The main sources of the fungi are contaminated poultry environments and moldy cereals that are given to the birds as supplementation. In planting season, farmers use most of their cereal seeds to plant farms; the remnants are for household use, and rejects are thrown to animals, including poultry. During wet periods, fungi multiply well and produce abundant spores. In harvesting periods, there are plenty of cereals, but poor storage conditions (humid and warm) favor fungal growth that can lead to poultry infections when bad grains are used as animal feeds.
**Diagnosis:** Clinical signs and lesions of aspergillosis can indicate the disease; confirmation is by microscopic demonstration of the fungus in the lesions or histologic sections.

Fungal species that can cause aspergillosis are *Aspergillus fumigatus*, and to a lesser extent, *A. flavus* and *A. niger*. Culturing the fungus from the lesions allows its identification. On Sabouraud’s dextrose agar (SDA) at 25°C, *Aspergillus* grows rapidly (within 2-5 days). Early growth of *A. fumigatus* is white and velvety. Later, when the conidia (spores) develop, the growth becomes blue-green to gray. Old cultures become dark brownish-gray and the texture ranges from velvety to granular or powdery. Colonies may be flat or folded. Isolates grow better at 37-45°C. Some strains grow at 65°C. Most isolates are sensitive to cycloheximide. Colonies of *A. niger* are white initially; later, when spores are produced, they become charcoal black, and are flat with a granular texture. The reverse side is colorless to white. Colonies of *A. flavus* are rough and woolly, and their surface is bright yellow to deep yellowish-green. The reverse side ranges from colorless to deep reddish-brown. Many isolates grow better at 37°C than at 25°C.

Microscopically, *Aspergillus* species produce thin, septate hyphae. Reproductive hyphae are called conidiophores. They arise from the vegetative mycelium, are thin-walled and may branch. They terminate in an inverted flask-shaped vesicle, from which sterigmata or phialides arise on the top half of the vesicle. There may be one (uniseriate) or two (biseriate) rows of sterigmata. Each sterigma bears long chains of conidia. This makes the conidiophore head look radiate.

**Treatment:** Clean and disinfect the house and spray it with 1:2000 copper sulphate or other suitable fungicide. Few or valuable birds can be treated with Nystatin or Amphotericin-B or other anti-mycotic agents. These are given together with antibiotics to prevent secondary bacterial infections.

The spread can be controlled by improving ventilation, eliminating the source of the infection, and adding a fungistat (mold curb, sodium or calcium propionate, or gentian violet) to the feed and/or copper sulfate or acidified copper in the drinking water for 3 days. The litter can be sprayed lightly with an oil-based germicide to control dust and air movement of fungal spores.

**Prevention:** It is important to thoroughly clean and disinfect the brooding area between broods. Use only clean litter, preferably soft wood shavings. Do not use sawdust, litter high in bark content, or shavings that have been wet. Move feeders and waterers periodically.

**Recovery:** Cases will re-occur whenever conditions are right for fungi to grow in feedstuffs or litter on the farm. If, however, the cause of the contamination is corrected and/or the source removed, there is no residual risk.

---

**Avian Encephalomyelitis**

**Other names:** epidemic tremor, AE.

**Clinical signs and lesions:** Signs commonly appear during the first week of life or in the second and third weeks. Affected chicks may first show a dull expression in the eyes, followed by progressive incoordination, sitting on hocks, tremors of the head and neck, and finally paralysis or prostration. Affected chicks are inactive. Some may refuse to walk or will walk on their hocks. In advanced cases, many chicks will lie with both feet out to one side (prostrate) and die. All stages (dullness, tremors, prostration) can usually be seen in an affected flock. Feed and water consumption decreases and the birds lose weight. In adult birds, a transitory drop (5-20%) in egg production may be the only clinical sign. However, in breeding flocks, a
corresponding decrease in hatchability is also noted, as the virus is egg-transmitted until hens develop immunity. Chickens which survive the clinical disease may develop cataracts later in life.

**Differential diagnosis:** Newcastle disease (neurologic form), equine encephalomyelitis, Marek's disease, and nutritional deficiencies may all resemble avian encephalomyelitis and should be excluded.

**Cause, transmission, and epidemiology:** The disease is most prevalent in chickens less than 6 weeks of age. Pheasants, coturnix quail, and turkeys are natural hosts as well, but less susceptible than chickens. Ducklings, young pigeons, and guinea fowl have been experimentally infected.

The virus can be transmitted through the egg from infected hen to chick, accounting for disease during the first week of life. The disease can also be spread through a flock by direct contact between susceptible hatchlings and infected birds, accounting for the disease at 2-3 weeks of age. Indirect spread can occur through fecal contamination of feed and water. Recovered birds are immune and do not develop clinical disease.

**Diagnosis:** Avian encephalomyelitis is definitively diagnosed by histopathology of the brain of infected and affected chicks. It can also be diagnosed by a correlation of typical clinical presentation and serology. Alternatively, yolk sac inoculation of embryonating chicken eggs with brain, pancreas and/or duodenum from infected birds will result in typical muscular dystrophy. The virus can be identified with PCR or electron microscopy in allantoic fluid.

**Treatment:** There is no treatment for outbreaks. Infected birds should be removed, killed and incinerated. Recovered chicks are unthrifty.

**Prevention:** A vaccine is available.

**Recovery:** Once a flock has been infected with avian encephalomyelitis on a premises, future flocks are likely to become infected both through the presence of the virus in the environment and also because chicks can get the virus from their dams. Vaccination is the best method to prevent the recurrence of clinical disease in new birds.

### Avian Influenza

**Other names:** influenza, bird flu, fowl plague, AI, HPAI, LPAI.

**Clinical signs and lesions:** Avian influenza is categorized as low (mild) or highly pathogenic. The low pathogenic form (LPAI) produces listlessness, loss of appetite, respiratory distress, diarrhea, transient drops in egg production, and low mortality. HPAI is seen mostly in chickens and turkeys, although it occurs in other birds, and is characterized by a sudden onset, massive morbidity and mortality over a short period of time. It causes facial swellings, blue combs and wattles, diarrhea, respiratory distress and sometimes nervous disorders. Dark red/white spots develop in the legs and combs of chickens. There can be blood-tinged discharge from the nostrils.

Mortality can range from low in the mild form to nearly 100% in the highly pathogenic form. Sudden exertion adds to the total mortality. Egg production and hatchability decreases. There can be an increase in production of soft-shelled and shell-less eggs.
Typical lesions of HPAI include swollen face, blue combs and wattles, red discoloration of the shanks and dead tissue on the lining of the proventriculus and gizzard.

**Differential diagnosis:** Avian influenza must be distinguished from Newcastle disease, as clinical signs and lesions are very similar. Low pathogenicity forms should also be differentiated from *Mycoplasma* infections (chronic respiratory disease) and fowl cholera.

**Cause, transmission, and epidemiology:** AI is caused by Type A influenza viruses. LPAI is caused by low pathogenic strains, and HPAI by the strains that are more deadly.

AI is transmitted by direct contract. Water bodies which have been contaminated with the virus from droppings of waterfowl and shorebirds, the natural carriers of the virus, are important sources of infection for domestic poultry. Direct contact between wild birds and free-range birds is another important factor in the spread of AI. It is also spread on the farm and between farms by contaminated farm equipment, feed bags, egg crates, vectors such as rodents and insects, and contaminated shoes and clothing. The avian influenza virus can remain viable for long periods of time at moderate temperatures, and can live indefinitely in frozen material. As a result, the disease can be spread through improper disposal of infected carcasses and manure.

Live or 'Wet' poultry markets where many species of birds are brought for sale in cities have the potential to be foci for the concentration and subsequent spread of the AI virus.

**Diagnosis:** In birds that have died from LPAI, mild to moderate inflammation of the respiratory tract and air sacs are seen, or there may be no lesions evident. The ovaries are inactive or inflamed.

Confirmation of tentative diagnosis based on symptoms and lesions can be made through isolation of the virus in chicken embryonated eggs, testing the virus for hemagglutination, and serological tests.

**Treatment:** There is no effective treatment for avian influenza. With the mild form of the disease, good husbandry, proper nutrition, and broad spectrum antibiotics may reduce losses from secondary infections. Recovered flocks will not shed the virus. This fact can be used to do a depopulation over time strategy, also known as controlled marketing. With a controlled marketing approach, infected flocks are moved to slaughter only after seroconversion, which stops virus shedding and thus prevents spread to new flocks. With the more lethal forms, strict quarantine and rapid destruction of all infected flocks remains the only effective method of stopping an avian influenza outbreak, although ring vaccination and the vaccination of replacement flocks may greatly enhance the chances of success. If you suspect you may have Avian Influenza in your flock, even the mild form, you should report it to the veterinarian's office. A proper diagnosis of avian influenza is essential. Aggressive action is recommended even for milder infections as this virus has the ability to readily mutate to a more pathogenic form.

**Prevention:** Strict biosecurity procedures should be practiced. Direct or indirect contact of susceptible birds with waterfowl, shorebirds, and birds or poultry products from endemic AI areas must be avoided. Vaccination programs used in conjunction with biosecurity have been used to control mild forms of the disease very successfully, although this approach must be planned in advance and include a surveillance plan. In most countries, vaccines may only be used with special permit.

**Recovery:** Recovery from an outbreak is accomplished through repopulation of farms with chicks from flocks that are not infected.
Avian Tuberculosis

**Other names:** TB, avian TB, avian mycobacteriosis

**Clinical signs and lesions:** Infected birds will be asymptomatic until late in the course of the disease. At late stages, infected birds may appear to be listless, depressed, and although they have a good appetite, they may be very thin. Affected birds may live for a few months or many years.

**Differential diagnosis:** Fowl typhoid, coligranuloma, Marek’s disease, aspergillosis

**Cause, transmission, and epidemiology:** Avian tuberculosis is caused by *Mycobacterium avium*, a slow-growing, acid-fast bacillus. The occurrence of the disease is sporadic, and usually occurs in aged birds. The bacilli are primarily in the tubercules (nodules) that line the intestinal tract of infected birds. The primary mode of spread is fecal-oral, but the disease can also be spread to new birds through cannibalism or contamination of the environment, especially with offal. The bacilli are environmentally stable and may survive up to 4 years.

**Diagnosis:** Diagnosis in living birds can be made with the tuberculin test, administered in the wattle. A presumptive diagnosis can be made on the appearance of lesions in the birds, and a definitive diagnosis can be made based on the appearance of acid-fast bacilli in typical granulomas and demonstrated with histopathology.

**Treatment:** Treatment is not recommended because this organism may be able to infect humans, particularly those who are immune suppressed, like HIV patients. Euthanasia is recommended.

**Prevention:** Prevention requires the introduction of tuberculosis-free birds only into the flock.

**Recovery:** Recovery from a case of tuberculosis should involve a complete depopulation of existing birds and clean up of the environment (particularly of old equipment), and introduction of birds from a tuberculosis-free source.

Botulism

**Other names:** Limberneck, Western duck sickness, bulbar paralysis, alkali disease.

**Clinical signs and lesions:** Signs appear within a few hours to a few days. In chickens, signs include drowsiness, weakness, and progressive loss of control of the legs, wings, and neck. Paresis soon progresses to paralysis, and the recumbent bird closes its eyes and appears to be in deep coma. Fine tremors of muscles and feathers occur in some birds. Death may occur quickly or may be delayed for a few hours. Most visibly affected birds die.

There are no gross lesions. A few birds might show mild enteritis. The crop may have putrid ingesta or maggots, but is usually empty.

**Differential diagnosis:** Botulism should be differentiated from psuedobotulism (transient paralysis), which is a manifestation of Marek’s disease.
Cause, transmission, and epidemiology: Botulism is a type of poisoning caused by ingestion of toxins produced by the bacterium Clostridium botulinum. In birds, botulism occurs frequently in captive pheasants and wild ducks, and occasionally in chickens. Except for vultures, most birds are susceptible. Most outbreaks in birds occur in growers or mature birds. In ducks and other waterfowl, occurrence is related to shallow water conditions in lakes with alkaline water and an excess of decaying vegetation.

Botulism occurs when the preformed toxins of C. botulinum are present in feeds, foods, dead poultry, or toxin-containing maggots. The toxin is extremely potent. The minimum lethal dose (MLD) for guinea pigs is 0.00012mg/kg subcutaneously (MLD for cobra venom is 0.002mg/kg). The toxin is relatively heat stable. Of the 8 types of toxin, Type C is the most common in poultry outbreaks.

C. botulinum is ubiquitous in nature and commonly present in feeds. When ideal conditions for growth occur, large amounts of exotoxin may be formed. If adequate toxin is consumed, botulism will develop. Improperly sterilized canned fruits and vegetables, spoiled animal feed, and decaying poultry carcasses can contain enough exotoxin to be highly lethal, even taken in small amounts.

It is speculated that wild waterfowl contract botulism when the toxin is consumed in decaying vegetation or dead fish in shallow, alkaline lakes as they dry up or are created by irrigation during the summer. Alternatively, it may be that the toxin is present in insects or crustaceans in the vegetation. Invertebrates killed by the anaerobic conditions contain toxin from growth of C. botulinum within them, and may be consumed by some waterfowl.

Ducks that die from various causes may be invaded after death by C. botulinum toxin type C normally present in their intestines. Toxins are formed in the carcasses. Ducks that feed on bits of the carcasses or on maggots from the carcasses may be poisoned. There is no spread from bird to bird.

Diagnosis: Saline gizzard or intestinal washings or blood serum from an affected bird can be tested for toxicity. Either can be injected into mice that have been both inoculated with protective antiserum and without antiserum. Results should clarify diagnosis.

Treatment: Remove spoiled feed or decaying matter. Provide Epsom salts (1 lb/1000 hens) in water or in wet mash. It has been reported that potassium permanganate (1:3000) in the drinking water is helpful. Affected birds can be treated with botulism antitoxin injections. Treatment of flocks with sodium selenite and vitamin A, D, and E or antibiotics has been reported to reduce mortality.

Prevention: The disease can be avoided by preventing access of poultry to any source of toxin. Sick and dead birds should be picked up and incinerated regularly and frequently because they are a common source of toxin. Control flies, prevent water leaks, replace feed if it is suspect, and keep birds away from shallow lakes with conditions that are optimal for toxin formation.

Recovery: Cases will re-occur if the conditions under which botulinum toxin is formed remain on the farm. If, however, the cause of the contamination is corrected and/or the source removed, there is no residual risk of botulism although the C. botulinum organism will remain.
Candidiasis

Other names: Thrush, crop mycosis, sour crop, soor, stomatitis, moniliasis.

Clinical signs and lesions: This is a mycotic infection affecting a wide variety of birds, man, and other animals. It usually affects the upper digestive tract as a secondary infection in birds, but also the reproductive tract in other animals. It is generally not a major clinical problem for a flock. The clinical signs are non-specific and include listlessness, poor appetite, stunted growth, unthriftiness, and ruffled feathers. The crop may be filled with a sour, fermentable odor.

Lesions occur in affected parts of the body, especially the crop, esophagus, mouth, pharynx, and sometimes in the proventriculus and intestines as thickening of mucosa, raised circular formations, or curdy, pseudomembranous dead tissue that can be peeled easily from the mucosa. The affected mucosa is often diffusely or focally thickened, raised, corrugated, and white. Necrotic epithelium may slough into the lumen as masses of soft cheesy material. The infected proventriculus is swollen, and has hemorrhagic mucosa which may be covered by catarrhal or necrotic material. Systemic and skin candidiasis has been reported. Lesions of other predisposing conditions may be present.

Differential diagnosis: Vitamin A deficiency and other upper gastrointestinal tract infections that may produce diphtheroid types of inflammations.

Cause, transmission, and epidemiology: Candidiasis is caused by a yeast-like fungus, Candida albicans, a ubiquitous organism which is a commensal organism in the gastrointestinal tract, skin, respiratory, and reproductive tracts of birds and mammals. Its overgrowth is prevented by normal bacterial microflora in the mucosal linings. Young birds are more susceptible than adults, although all ages are affected. It is often associated with other disease problems, especially bacteria that produce endotoxins, physiological disorders, long-term oral antibiotic administration in drinking water, immunosuppression, lack of good sanitation, heavy parasitism, vitamin deficiency, high carbohydrate diets, and debilitating conditions that may alter the bacterial flora in the bird.

Diagnosis: Lesions and the presence of fungal mycelium may be adequate. The fungus can be cultured on Sabouraud’s dextrose agar. At room temperature or 37°C, growth occurs in 1-3 days. Colonies are smooth, white to creamy, and moist and pasty, resembling those of bacteria. On further incubation, colonies become furrowed and roughened. When observed with a dissecting microscope, filaments that are submerged in the agar may be seen. Microscopically, large oval budding cells, occurring singly or in clusters, are seen. Commonly buds do not detach, but elongate to form pseudohyphae, from which lateral or terminal chlamydospores are produced.

Treatment: Control primary disease causes or conditions. Use copper sulphate or Nystatin for treatment.

Prevention: Practice good sanitation, hygiene, prevent overcrowding; and use phenolic and iodine preparations to sanitize equipment. Avoid unnecessary use of antibiotics, other drugs, and anticoccidiostats. Supplementation with probiotics to replace flora after antibiotics may be beneficial.

Recovery: Cases will re-occur if the original causes are still present. If, however, the cause of the disease is corrected, there is no residual risk to future flocks on the farm.
Cannibalism

Cannibalism is a common problem in dense poultry populations, such as found in commercial settings, but occurs only sporadically in village flocks.

Clinical signs and lesions: A vice of chickens, turkeys and other birds raised in captivity, that results in loss of tissues from pecking and plucking of feathers (wings, tail, and other parts of the body), and pecking of the vent, toes, and head region.

Feather Picking is a behavior expressed by dominant birds toward subordinates. It varies from pecking to plucking the feathers of subordinate birds. Light chicken breeds (white leghorns) are more prone than heavier breeds (brown hybrids). Vent picking occurs in laying birds. It is common when birds raised in floor systems lay their eggs on the floor in crowded areas. This occurs after oviposition, when exposed mucus membranes stimulate pecking by other birds. Toe picking occurs commonly in young birds, while head picking is more common in older birds, especially those housed in cages.

Severely damaged or missing feathers, and hemorrhages or scabbing on the head, wings, tail, vent, and other body areas are characteristic signs. Feather picking, if severe, can result in fatal hemorrhage in any age of bird. Vent pecking may result in birds eating off portions of the intestines, resulting in death of the affected bird. Birds dying of cannibalism may have anemia, blood stained feathers, and may have extruded visceral organs. Affected birds have poor thermoregulation, greater energy demands than others, and affected hens decrease or end their egg production.

Differential diagnosis: Traumatic body injuries and diseases causing hemorrhagic diarrhea.

Cause, transmission, and epidemiology: The behavior is learned between birds, although the initiating cause is not clearly known. Cannibalism is associated with overcrowding, bright light, temperature extremes, pelleted or compressed feed, mineral and nutritional deficiencies, irritation by external parasites, injuries, and limited resources.

Diagnosis: Diagnosis is based on the appearance of typical injuries and by ruling out trauma.

Treatment: Wounds on individual birds can be treated with topical cleaning and bandaging, but that is usually not practical.

Prevention: Through proper husbandry:

- Reduce light intensity
- Provide perches as a refuge for pecked birds
- Avoid overcrowding and provide adequate feeder and waterer space.
- Environmental enrichment with pecking devices
- Beak trimming before 5 weeks of age
- Provide a refuge for young birds in mixed age groups

Recovery: Cull birds with severe injuries. Remedy contributing factors as listed in prevention.
Chlamydiosis

Other names: ornithosis, psittacosis, parrot fever.

Clinical signs and lesions: Clinical signs in most birds include nasal-ocular discharge, conjunctivitis, sinusitis, diarrhea, weakness, loss of body weight, and a reduction in feed consumption. In turkeys there is also respiratory distress and loose yellow to greenish-yellow colored droppings. Chlamydiosis runs rather slowly through turkey flocks, with a maximum incidence of around 50%.

Differential diagnosis: Chlamydiosis can clinically present similarly to fowl cholera, especially in turkeys. Viral infections (Newcastle disease, avian influenza, infectious bronchitis, swollen head syndrome) or mycoplasmosis with colibacilosis may present similarly.

Cause, transmission, and epidemiology: Chlamydiosis is caused by the bacterium Chlamydia psittaci. The disease was formerly called psittacosis or parrot fever when diagnosed in psittacine (curve-beaked) birds, and ornithosis when diagnosed in all other birds or in humans. Currently, the term chlamydiosis is used to describe infections in any animal. Affected species include turkeys, pigeons, ducks, psittacine (curve-beaked) birds, captive and aviary birds, many other bird species, and other animals. Chickens are not commonly affected. Humans are susceptible, especially older or immunosuppressed individuals who are at a higher risk. Chlamydiosis in humans is an occupational disease of turkey and duck growers, haulers, and processing workers in the live-bird areas, and of workers in pet-bird aviaries, although the incidence is rare.

The primary means of transmission is through inhalation of fecal dust and respiratory tract secretions. It can also be transmitted on contaminated clothing and equipment. Recovered birds remain carriers and will continue to intermittently shed the infective agent for long periods after clinical signs have subsided. Environmental stress may provoke a recurrence of the disease.

Diagnosis: Chlamydiosis is definitively diagnosed by isolation and identification of Chlamydia psittaci in cell cultures or embryonating chicken eggs. However, this can be time consuming; the typical appearance of this organism with Giemsa or Jimenez staining makes the staining of tissue imprints a rapid and accurate method of making a diagnosis.

Treatment: Chlortetracycline can be given in the feed (200-400 g/ton) for 3 weeks. Other antibiotics are usually ineffective. Recovered birds are safe to eat. Permanent lesions on the heart and liver are not infectious. Withdrawal periods for any medications used must be strictly observed to avoid residual chemicals in the tissues.

Prevention: A vaccine exists but is not readily available in Africa. Have a good biosecurity program, and exclude wild birds as much as possible.

Recovery: Because recovered birds may remain carriers, new birds should only be introduced to the premises after all of the birds from previous flock have been removed and the environment fully cleaned and sanitized.
Colibacillosis

Older birds frequently suffer from diseases caused by *Escherichia coli*. These conditions can be gastrointestinal, dermatological, or asymptomatic disorders, but *E. coli* may also invade the blood, clinical signs consistent with septicemia may be observed in affected birds. Colibacillosis is frequently secondary to a primary infectious disease agent and the signs of disease may include those caused directly by *E. coli* as well as the signs of the primary agent.

*Other names:* *E. coli* septicemia, peritonitis, air sac, cellulitis, Hjarre's disease, coligranuloma

*Clinical signs and lesions:* These include diarrhea, inappetence, unthriftiness, respiratory difficulties, drowsiness, and reduced egg production. Mortality is usually high.

In colibacillosis in growing broilers, the intestine is often bloated, thin walled, and contains watery or mucoid material tinged with blood. The air sacs, peritoneum and pericardium are thickened and may have caseous deposits. The pericardium is also thickened and yellow-white in color. Abdominal organs are swollen and may be covered with a layer of fibrin.

*E. coli* can also cause cellulitis, especially in meat birds. The primary lesion is usually a scratch or other trauma to the skin. Layers of cheesy material develop just under the skin. Cellulitis is most common in densely housed birds.

Coligranuloma or Hjarre's disease causes nodules on the intestine and is a rare manifestation of *E. coli* infection.

*Differential diagnosis:* Fowl cholera, pullorum disease, chronic respiratory disease.

*Cause, transmission, and epidemiology:* *E. coli* disease in growing birds is caused by avian-pathogenic *E. coli* serotypes. These are not the same serotypes that cause public health outbreaks. Transmission is usually fecal-oral and often involves a contaminated environment.

*Diagnosis:* Bacterial isolation and identification of *E. coli* from the intestinal and visceral organs constitute definitive diagnosis.

*Treatment:* For *E. coli* disease, antibacterial therapy is normally successful. Local patterns of antibiotic resistance should be considered with selecting antibiotics for use in poultry flocks. The most effective antibiotics should be selected and used for the recommended period of time and at the correct dose.

*Prevention:* Hygiene, farm biosecurity and controlling primary infectious diseases like Newcastle disease and infectious bronchitis are important in controlling these diseases.

*Recovery:* A complete depopulation of the facility at the end of a flock's life and disinfection followed by resting of the premises can reduce the environmental load of *E. coli* but it will not be eliminated. For full recovery, the primary cause of the disease must be controlled.
Cryptococcosis

Other names: Torulosis, torula, yeast meningitis, European blastomycosis.

Clinical signs and lesions: Cryptococcosis is a disease of humans and animals. It has been reported mostly in zoo and pet birds (pheasants, fowl, house martins, jackdaws, chaffinches, canaries, pigeons and psittacines), but not in other birds. It is of public health importance and occurs in poultry environments. This is a systemic fungal disease that may affect the lungs, central nervous system, and skin.

It has been reported in pheasants with enterohepatitis. Chickens experimentally infected have granulomas and necrotic processes in the liver, intestines, lungs, and spleen.

Differential diagnosis: Other lung infections and systemic fungal infections such as aspergillosis, histoplasmosis, and dactylariosis.

Cause, transmission, and epidemiology: The causative agent is Cryptococcus neoformans, an imperfect yeast that reproduces by budding, resulting in spherical cells surrounded by a thick mucilaginous capsule. The cell diameter is 4-6 µm, and the capsule is 1-2 µm thick. It is commonly isolated from pigeon nests and dropping sites.

Diagnosis: Culturing of the organism, histopathology, and demonstration of its thick capsule and deep red budding spore using mucicarmine stain. The fungus grows well within 48 hr at 30 °C on glucose agar.

Treatment: Treatment is of little value.

Prevention: Because this disease occurs sporadically and specific risk factors have not been identified, there are no preventative measures that can be recommended. However, the isolation of infected individuals from a group may prevent spread to more individuals.

Recovery: There is no residual risk to birds placed in an environment that has previously had a case of cryptococcosis.

Dactylariosis

Clinical signs and lesions: This is a neurotrophic mycotic disease of turkey poults, quail chicks and young chickens, with many of the clinical and pathologic features of aspergillosis. Signs of dactylariosis are incoordination, tremors, torticollis, circling, recumbency due to mycotic lesions in the brain, and death.

Lesions sometimes occur in the air sacs, lungs, liver and eyes (globe) as granulomas. In the brain, lesions appear on the cerebellum and cerebrum as large, hardened, grayish, circular areas, or as red focal areas.

Differential diagnosis: Aspergillosis.

Cause, transmission, and epidemiology: The etiological agent is Dactylaria gallopava; it grows naturally in old sawdust, which often is used as chicken litter. Occurrence of this disease is associated with contaminated litter (wood chip and sawdust) and egg incubators. The organism grows well in moist, acidic environments with moderately high temperatures.
Diagnosis: The fungus can be cultured on Sabouraud’s dextrose agar at 25 °C and 37 °C or at 45 °C. Growth is inhibited by cycloheximide. Colonies are velvety, gray-brown with a flat or wrinkled surface, and the reverse side of the colony is a deep purple-red. Light tan to brown septate mycelium and oval, two-celled brownish conidia (3.2 x 9.0 µm) on unbranched conidiophores are seen under the microscope.

Treatment: Remove contaminated litter and decontaminate incubators by fumigation.

Prevention: Good sanitation.

Recovery: Cases will recur if fungi can grow in incubators or in litter on the farm that is not handled properly. If, however, the cause of the contamination is corrected and/or the source removed, there is no residual risk to new birds.

Duck Enteritis

Other names: Duck plague.

Clinical signs and lesions: Duck enteritis is an acute herpesvirus disease of ducks, geese, and swans. Symptoms vary by age of the birds, with ducklings showing diarrhea (sometimes resulting in a blood-stained vent area), dehydration, and cyanotic (blue colored) bills. In adult ducks there is a marked drop in egg production. Sudden high mortality in the flock may be the first sign of the disease. Sick birds show weakness, anorexia, ataxia, tremors, photophobia, adhered eyelids, ruffled feathers, nasal discharge, excessive thirst, and watery diarrhea leading to staining of the vent. Mature males may have prolapse of the penis. Affected birds become too weak to stand, have drooping wings, and hang their heads down. Morbidity and mortality can reach 100%, but may be as low as (5%). Most birds that develop clinical signs die within 1-5 days.

On postmortem examination, hemorrhages are common, especially on the liver, gastrointestinal mucosa, ovaries, heart (including pericardium, myocardium, endocardium, and valves), and in the annular bands of lymphoid tissue along the intestines, which may also show necrosis. Petechiae are common on the surfaces of the liver, lungs, pancreas, and intestine. Free blood may occur in the body cavities, gizzard, or intestines. Edema may be seen in the cervical region, and severe enteritis can occur. Crusty, elevated plaques are sometimes evident in the esophagus, ceca, rectum, cloaca, or bursa of Fabricius. Because of the loss of blood, the spleen is sometimes reduced in size, dark, and mottled. After initial petechial hemorrhages develop, the liver becomes bile-stained with scattered small, white foci.

Differential diagnosis: Duck viral hepatitis, pasteurellosis (fowl cholera), Newcastle disease, avian influenza, coccidiosis, and other causes of enteritis are all possible differential diagnoses, depending on the clinical presentation.

Cause, transmission, and epidemiology: Duck viral enteritis is caused by several strains of herpesviruses that have similar characteristics. The virus is transmitted between infected birds or by contact with contaminated environments, especially bodies of water. Wild ducks may act as carriers for up to one year after infection, perhaps shedding virus during periods of stress. There is a possibility that the disease may be transmitted by biting insects feeding on viremic birds.

All breeds of ducks are affected. All age groups and many varieties are susceptible; however, mostly adult ducks are affected. It has been suspected in Kenya and other African countries.
**Duck Viral Hepatitis**

*Clinical signs and lesions:* DVH is a severely acute viral infection causing hepatitis in young ducklings (under 5 weeks of age). It spreads rapidly with short duration and high mortality. It is probably present in all major duck-raising areas of the world. In Africa it has been suspected in Kenya and Tanzania.

Three different viruses are known to cause disease:

**DVH type 1:** Has a rapid onset — around 24 hr post-infection — with morbidity close to 100% and most mortality occurring within 1 week of onset. While up to 90% of ducklings under one week of age die, mortality decreases with age, and is negligible in birds over 4 weeks of age. Some older ducklings may not show clinical signs, and adult breeders do not become clinically ill. Death often occurs within 1 hr of the appearance of signs. Sick ducklings squat with partially closed eyes. Soon they fall onto their sides, exhibit spasmodic kicking movements, and die. Chickens and turkeys are resistant.

**DVH type 2:** Clinical signs usually appear within 1-4 days post-infection, and mortality can occur within 1-2 hours of signs of illness. Almost all birds with clinical signs die; mortality varies from 10-50%. Ducklings exhibit convulsions and opisthotonus.

**DVH type 3:** This variant is less severe than DVH type 2; mortality is rarely over 30%. Infected ducklings show similar symptoms to those caused by DVH type 1, and gross pathological symptoms are similar.

All three viruses cause similar lesions, mostly affecting the liver, which becomes swollen with petechial or diffuse hemorrhages, as well as microscopic necrosis and bile duct proliferation. The kidneys may also be swollen, and the spleen may be enlarged.

**Differential diagnosis:** Duck viral hepatitis must be differentiated from duck viral enteritis, Newcastle disease, and avian influenza.

**Cause, transmission, and epidemiology:** DVH type 1 is a highly contagious disease. It is caused by an enterovirus in the family Picornaviridae. It is chloroform resistant and does not hemagglutinate, features that help separate it from most other viral diseases of ducks. The virus is excreted by recovered ducklings for up to 8 weeks after onset of infection. Susceptible ducklings can become infected by contact with
infected ducklings or their contaminated pens. The virus is stable for long periods of time in normal environments and is difficult to eliminate from contaminated premises. It can survive for 10 weeks in contaminated brooders and for 37 days in feces.

DVH type 2 is caused by an astrovirus. It is transmitted via both the oral and cloacal routes. Survivors excrete virus for up to 1 week post-infection. As with DVH type 1, the virus persists in the environment.

DVH type 3 is similar to, but less severe than DVH type 2. It is caused by a picornavirus unrelated to DVH type 1 virus.

**Diagnosis:** The sudden onset, rapid spread, short course, and focal, hemorrhagic hepatitis in young ducklings are highly suggestive of a diagnosis of DVH. DVH type 1 can be isolated in embryonating chick or duck embryos or 1-day old susceptible ducklings and identified by serum neutralization test. The direct FA technique, when used on livers of either naturally occurring cases or inoculated duck embryos, yields rapid and accurate results. DVH type 2 can be identified by the detection of astrovirus particles in liver homogenates by electron microscopy. DVH type 3 cannot be isolated in chicken embryos. It has been cultured in liver and kidney cell cultures from duck embryos or ducklings. Chorioallantoic membrane inoculation of duck embryos are the preferred route of isolation.

**Treatment:** DVH viruses stimulate a high degree of immunity in ducklings that survive infection and in inoculated adult ducks. A potent antiserum can be made from the blood of such ducks. The blood can be collected at slaughter and sera harvested. Antibodies for prophylactic use may also be obtained from the yolk of eggs produced by immune breeders, or from the eggs of chicken hyperimmunized with the virus. DVH type 1: In the initial stages of the outbreak, all susceptible ducklings should be inoculated intramuscularly with duck hepatitis viral antiserum. One inoculation should be adequate if the antiserum is potent. For DVH types 2 and 3, convalescent sera obtained from infected ducks has been used to effectively control outbreaks in the field.

**Prevention:** Usually, exposed breeders will produce resistant progeny, so farmers should obtain stock from exposed or vaccinated breeders. Unexposed ducklings can be actively immunized using a chicken-passaged attenuated vaccine. However, young ducklings with parental immunity may not respond to vaccination. Strict biosecurity procedures should be employed. An experimental vaccine is not available commercially.

**Recovery:** Eradication of DVH from a premises has been demonstrated with extensive cleaning and sanitation, implementation of strict biosecurity to prevent new introductions, and the vaccination of breeders. DVH type 2 has been successfully eliminated from contaminated premises through a combination of standard disinfection and fumigation with formaldehyde. However, vaccination may be a more practical way to limit the impacts of the disease.

**Ectoparasites**

These are external parasites of poultry. Ectoparasites found on poultry are in the phylum Arthropoda, which is characterized by having segmented bodies, jointed appendages, and a chitinous exoskeleton. Two classes of arthropods affect poultry: the *Insecta*, which includes the orders Phthiraptera (lice), Siphonaptera (fleas) and Diptera (flies, including mosquitoes); and the *Arachnida*, including the order Acarina (ticks and mites).
Ectoparasites are very common in free-range management systems, and usually less so in commercial systems. These parasites can transmit a number of infectious diseases and can also act as transport/intermediate hosts of a range of helminth parasites. Although they are believed to occur in many family poultry flocks, only a few publications are written on their prevalence or occurrence in African countries.

**INSECT ECTOPARASITES:**
The insects that most often affect poultry are lice, fleas, mosquitoes, and other flies.

**Ectoparasites: Poultry Lice**
All species of lice that affect chickens are in the suborder Mallophaga, and have mouthparts adapted for chewing. They feed on the epithelial debris of the skin of the host, or on feathers. The meso- and metathorax are fused to form one piece behind the prothorax, which is a distinct and separate segment. Lice species affecting chickens include *Menacanthus stramineus*, *Menopon gallinae*, *Cuclotogaster heterographus*, *Lipeurus caponis*, *Goniodes gigas* and *Goniocoites gallinae*.

**Published occurrences in Africa:**

**Etiological characteristics:**
1. *Menacanthus stramineus* is relatively large, with adults about 3.5 mm in length. It occurs on those parts of the body which are not densely feathered, like the breast, thigh, and around the vent. Its palpi and four-segmented antennae are distinct. The abdominal segments each have two dorsal rows of medium-length bristles. The eggs have filaments on the anterior half of the shell and on the operculum.
2. *Menopon gallinae* occurs largely on the body, thigh, and breast feathers. The adult is about 2 mm in length and pale yellow in color. It has small palpi and a pair of four-segmented antennae folded into grooves in the head. The abdomen has a sparse covering of small to medium-length setae.
3. *Cuclotogaster heterographus* occurs on the head. It has a rounded body with a large, round head. The adult is about 2.5 mm in length. Three long bristles project from each side of the dorsal surface of the head. The abdomen is barrel-shaped in the female and more elongate in the male.
4. *Lipeurus caponis* is an elongated, narrow species, about 2.2 mm in length and 0.3 mm in width. It occurs on the underside of the large wing feathers and moves about very little. The legs are narrow and, characteristically, the hind legs are about twice as long as the first two pairs. There are characteristic small angular projections on the head in front of the antennae.
5. *Goniodes gigas* are large brown lice, about 3 mm in length, and occur on body feathers. The head is concave posteriorly, producing marked angular corners, and carries two large bristles projecting from each side of its dorsal surface. Its antennae have five segments.
6. *Goniocoites gallinae* is the smallest species of lice found on poultry, with adults measuring 1 to 1.5 mm in length. The head is rounded, carrying two large bristles that project from each side of its dorsal surface. The antennae have five segments.
Clinical signs and pathology: On the host, lice cause pruritus, scratching, excoriation, secondary feather damage (as birds pluck their feathers), and irritation, which lead to self-wounding and resultant formation of inflamed and scab covered skin. Chicken lice feed on dry scales, feathers, or scabs on the skin. As lice crawl over the bird, their mouthparts and sharp claws scratch the skin. This constant irritation causes the bird to become nervous and behave abnormally, causing a general unthriftness and unkempt appearance. Infestation in birds also leads to a drop in egg production, decreased hen weight, decreased clutch size, and death in young birds. *Menacanthus stramineus* can cause anemia by puncturing soft feather quills and feeding on the blood that oozes out.

Heavy louse infestations may cause feather damage and irritation but more importantly, are a sign of debility and poor husbandry. They can move directly between hosts or “hitch lifts” on hippoboscid flies.

Life cycle and epidemiology: Lice are permanent ectoparasites, spending their entire life cycle on their hosts. They tend to remain with single host bird throughout their lives; they are unable to survive for more than 1-2 days off their host. Eggs hatch in 5 to 7 days. Their life cycle from egg to adult is about 3 weeks. As many as 60 eggs are laid by each adult female louse and are glued to the host feathers. A pair of lice may produce 120,000 descendants within a few months.

Diagnosis: This is based on clinical signs and identification of lice in plumage, and their eggs (nits) attached to feathers.

Treatment and control: Control of poultry lice requires treating the birds, since lice remain on the bird throughout its life. Birds may be sprayed, dusted, or dipped with an appropriate insecticide like permethrin, carbaryl, malathion, or rotenone. Because lice live only a few days off the host, emptying a shed or yard for a week will clean it.

Ectoparasites: Poultry Fleas

*Echidnophaga gallinacea* (stick tight flea) is the only flea commonly affecting poultry. It may infest a wide variety of birds and mammals. Poultry, rodents, rabbits, dogs, cats, horses, and occasionally humans may all become infested. Poultry may develop clusters of the fleas around the eyes, comb, wattles, and other bare spots. *Echidnophaga gallinacea* are difficult to remove because their mouthparts are deeply embedded in the host’s flesh and they cannot be brushed off.

Occurrence: *Echidnophaga gallinacea* is found throughout the tropics and subtropics. It has been reported in Nigeria, Kenya, and Tanzania.

Etiological Characteristics: Adults are approximately 1.5 to 4 mm in length, laterally flattened, and are black to brown in color. Their head is sharply angled at the front. There are no genal or pronotal ctenidia. On the head behind the antennae are two setae, and in females, a well-developed occipital lobe. Thoracic segments are narrowed dorsally. Mouthparts appear large, extending the length of the forecoxae and projecting from the head conspicuously. The maxillary laciniae are broad and coarse.

Clinical signs and pathology: The adult fleas attach to the skin around the face and head, causing severe irritation, nodular formation, and in some cases, blindness. They can cause blood loss, anemia, and even death. The skin over the nodules often becomes ulcerated, and young birds may be killed by heavy infestations.
Life cycle and epidemiology: Upon fertilization, the female fleas burrow into the skin of the fowl, mainly on the comb, wattles, and around the eyes of the birds, resulting in the formation of nodules in which eggs are laid. Hatching occurs within the nodules. The female lays up to 20 eggs at a time and about 400-500 total during her lifetime. Larvae drop to the ground to develop in soil around chicken cages, pupating in two weeks. Adult fleas emerge from the pupae and are free-living until breeding occurs. Female fleas then attach to the host and lay eggs to complete the cycle.

Diagnosis: This is based on history, clinical signs, and identification of fleas or flea feces on birds.

Treatment: Managing fleas on birds requires an integrated approach. Both the host bird and the environment must be treated at the same time to be effective. Birds and surroundings should be sprayed with insecticide. Control the fleas by treating the birds, removing them from the infested area for three weeks, and treating the area (removing fecal droppings and litter, and spraying a suitable insecticide) and birds (again) before returning them. Domestic animals having contact with poultry should be treated at the same time. A range of insecticides can be used for flea control on the birds: organophosphates, carbamates, pyrethrins, and pyrethroids.

Ectoparasites: Mosquitoes and Other flies

The order Diptera includes, among others, the families Culicidae (mosquitoes), Simuliidae (black flies), Ceratopogonidae (midges), and Muscidae (house flies and stable flies). Most of these insects are found in poultry houses, where some feed on birds and other animals (including humans), especially at night. Others contaminate the feed and water in the poultry rearing areas.

Clinical signs, pathology and economic importance: The majority of these flies irritate the host by biting and sucking blood. They cause annoyance and physical damage to setting hens and young birds. Their greatest importance lies in their role as intermediate hosts or as mechanical vectors of disease agents.

Mosquitoes (Aedes spp., Anopheles spp., and Culex spp.), may act as intermediate hosts for Plasmodium spp., and mechanically transfer fowl pox virus.

Black flies and biting midges are intermediate hosts of the protozoan Leucocytozoon spp. Biting midges are vectors for fowl pox, avian infectious synovitis, and Haemoproteus spp.

Flies in the family Muscidae may transfer Newcastle disease virus, Heterakis gallinarum, Pasteurella multocida, and Mycobacterium avium to non-infected birds.

Diagnosis: Clinical signs and identification of feeding flies, especially at night. Traps can be used to collect and identify flying insects in the vicinity of poultry.
ARACHNID ECTOPARASITES:
Arachnids include mites and ticks, some of which affect poultry.

**Ectoparasites: Poultry Ticks**

1. *Argas persicus* (fowl tick) commonly affects chickens, turkeys, pigeons, ducks and geese in tropical and sub-tropical countries. In Africa they are found in Egypt, Kenya, Zimbabwe, and Nigeria. *A. walkerae* and *A. reflexus hermanni* are reported from West Africa. They are found on the skin (especially nymphs and larval stages), but most of the time the ticks hide in cracks in houses, market stalls and sheds, or under tree bark, away from the host.

**Etiological Characteristics:** The unfed adult tick is pale yellow, turning reddish brown when fed. The female tick is about 8 mm in length, while males are 5 mm. The margin of the body appears to be composed of irregular quadrangular plates or cells, and the hypostome is notched at the tip.

**Clinical signs and pathology:** *Argas persicus* causes severe blood loss leading to progressively lower egg production and/or weight gain. The affected birds are ruffled, with poor appetite and diarrhea. This species can produce tick paralysis in chickens.

2. *Ornithodoros* species (the eyeless tampan) affect poultry and other domestic and wild animals. These ticks occur in tropical and subtropical habitats. They are found on the skin, but most of the time, the ticks hide in cracks or under the tree bark, away from the host. This species is not well documented in Africa.

**Etiological Characteristics:** The integument has wrinkled patterns that run continuously over the dorsal and ventral surfaces. There are no distinct lateral margins of the body, which appears sac-like. These parasites transmit *Borrelia anserina* and *Aegyptinella pullorum*.

**Clinical signs and pathology:** *Ornithodoros* spp. cause anemia, emaciation, weakness and slow growth.

**Life cycle and epidemiology of these tick species:** Females lay eggs in the cracks and crevices they occupy, usually in batches of 30 to 100 or more; they lay several clutches of eggs and produce an average of 700 to 800 eggs during their lifetime. A blood meal is needed to produce each clutch of eggs. Eggs hatch in 2 to 4 weeks, and 6-legged tick larvae appear. Larvae are active day or night and readily seek a host. After attaching to the host, larvae feed for 5-6 days. They then drop from the host and molt to the nymphal stage. Nymphs have 8 legs, and feed only at night for short periods. After two more nymphal molts, the ticks reach the adult stage. Under favorable conditions, the time from egg to adult is approximately 30 days. Adult ticks completely engorge on hosts in 30 to 45 minutes. They are extremely resistant to starvation, and can live more than a year without a blood meal.

**Diagnosis:** This is based on history, clinical signs, collection and identification of ticks from the skin. Larvae can be seen attached to the skin, especially on unfeathered or more sparsely feathered areas of the body (head, breast, abdomen, cloaca), but not on the leg shanks. They are nocturnal feeders, so examination of birds at night is necessary for diagnosis, especially in cases of low-density infestations.

**Treatment:** Treat birds, poultry shed(s), and all housing with insecticide, making sure that all cracks are penetrated. Nesting material should be removed and burnt or buried. Treatment must be repeated after seven days to break the life cycle. A follow-up treatment at one month is also necessary. Spray captive birds in contact with family poultry to prevent re-infestation of the flock.
Ectoparasites: Poultry Mites

The common free-living ectoparasitic mites of poultry belong to the family Dermanyssidae, and include the chicken mite, northern fowl mite, and tropical fowl mite. These mites possess relatively well-sclerotized free dorsal and ventral plates, claws and caruncles on the tarsi, one lateroventral stigma near each third coxa, and small chelicerae on long-sheathed bases. They are found on different parts of the body, and most species are either microscopic or less than 1 mm in length. Of lesser importance are members of many other mite families that bore into the skin or infect various internal passages and organs.

Species found on the skin include Dermanyssus gallinae, Ornithonyssus sylviarum, and Ornithonyssus bursa. They affect chickens, turkeys, ducks and other domestic and wild birds.

Etiological characteristics: Dermanyssus gallinae (chicken mites) are quite small, but they can be seen with the naked eye. They can be identified by the shape of the dorsal plate and by the long whip-like chelicerae, which look like stylets. The adult measures about 0.7 x 0.4 mm, varying in color from gray to deep red, depending on its blood content. Dermanyssus gallinae is cosmopolitan in distribution and has been reported in Tanzania, Nigeria, Zambia, and Kenya.

Ornithonyssus (Liponyssus) sylviarum (northern fowl mite) is recognized as a serious pest in temperate countries, and is extremely common in almost all types of commercial production facilities. It is easily distinguished from Dermanyssus gallinae by the possession of obviously visible chelicerae, and the shape of the dorsal and anal plates. To date it has not been reported in Africa.

Ornithonyssus bursa (tropical fowl mite) is distributed throughout the warmer regions of the world and possibly replaces O. sylviarum in these regions. The hosts include poultry, pigeons, sparrows, and humans. It closely resembles the Northern fowl mite, but can be distinguished by the shape of the dorsal plate and the pattern of the setae. Ornithonyssus bursa occurs in the tropics and subtropics and has been reported in Zambia and Nigeria, while O. sylviarum occurs in temperate regions.

Cnemidocoptes gallinae (feather mites or depluming mites) are common mites observed in chickens, but are also found in pheasants, pigeons, and geese. Females are rounded and about 400 microns long. The legs are short and stubby, and the anus is terminal. The dorsal surface is covered by faint striations, but mid-dorsally the striations are unbroken. The body has no spines or scales. Stalked pulvilli are present on all legs of larvae and males, but are absent in the nymphal stages and females. Copulatory suckers are absent in male.

Cnemidocoptes mutans (scaly-leg mite) lives under the scales on the feet and legs of birds, causing thickening that give the impression that the scales are protruding outwards. It also attaches to the comb, wattles, and neck. Cnemidocoptes mutans is characterized by short stubby legs, the terminal anus, and the dorsal surface covered by faint striation. Mid-dorsally, the pattern of dorsal striations is broken in a plate-or scale-like pattern. The body has no scales or spines. Cnemidocoptes mutans has been reported in Zimbabwe, Tanzania, Zambia and Kenya.

Cytodites nudus (airsac mites) are found in air passages and lungs of wild birds and poultry. The mite is oval and about 500 microns long, with a smooth cuticle. The chelicerae are absent, and the palps are fused to form a soft sucking organ, through which fluids are imbibed. This mite has been reported in Kenya.

Life cycle and epidemiology: Mites do not spend their entire life cycle on the host bird, except for Cnemidocoptes mutans and Ornithonyssus spp. Adult mites spend most of their lives on the host, but will
wander off the birds into crevices and cracks. Adult female mites complete egg-laying in 2 days; the number of eggs laid averages 2 to 5 per female.

*Dermanyssus gallinae* (chicken mites) are gregarious and can be found in large numbers around poultry. The life cycle is fairly complicated, with a series of feeding and non-feeding immature stages. Eggs hatch in about 3 days, and the life cycle can be completed in 7 to 10 days under favorable conditions. Adults are resistant to starvation, and can live away from the host for more than a month.

*Ornithonyssus sylvarium* breeds continuously on the host bird, and is a particular problem for caged birds. The mites spend their entire life cycle on the host. After laying eggs, normally on feathers on the cooler regions of the bird, the mites migrate to the neck area. The eggs hatch within a day, with both larval and nymphal stages completed in four days, and the entire life cycle completes within a week.

*Ornithonyssus bursa* can pass its entire life cycle on chickens. Its biology and habits are similar to those of *Ornithonyssus sylvarium*, although a greater proportion of its eggs are laid in the nests.

There is some evidence that lice may prey on mites, explaining why the two are rarely observed on the same host.

**Clinical signs and pathology:** *Dermanyssus gallinae* are bloodsuckers and are irritating to poultry. Anemia occurs in heavily parasitized birds, reducing feed efficiency, egg production, and the ability to withstand and overcome diseases. Birds infected with some mites will have a change of behavior due to the itching caused by the mites.

On birds heavily infested with *Ornithonyssus sylvarium*, inspection can reveal heavy deposits of mite eggs and feces in the vent area. Parting of the feathers reveals the mites, eggs, and excrement. The mites can also be seen crawling on eggs. The northern fowl mite is sometimes confused with the red mite, although unlike the red mite, it can be found easily on birds in the day as well as night. Heavy infestations result in blackened feathers and scabby and cracked skin, particularly around the vent, and infested male birds may be discouraged from breeding. *Ornithonyssus sylvarium* and *O. bursa* are associated with severe emaciation, droopiness, and reddened scabby skin in chickens.

*Cnemidocoptes gallinae* mites are also associated with severe emaciation, droopiness, and reddened scabby skin in chickens. These mites burrow into the epidermis at the base of feather shafts, and cause intense irritation and feather pulling in chickens, pheasants, pigeons, and geese.

*Cnemidocoptes mutans* mites cause inflammation with exudates and subsequent keratinization of the legs. Pathological findings include small yellowish-grey or reddish-brown, wart-like skin proliferations that seem to begin on the soft parts of the plantar side of the tarsus and spread along the digits and up the shanks to the hock. There is elevation of the scales and increased desquamation.

Small infestations with *Cytodites nudus* may cause coughing and accumulation of mucus in trachea and bronchi. The affected air sacs are cloudy and may have some fibrin deposition. The bird’s balance may be affected.

**Diagnosis:** This is made on the basis of clinical features and by finding mites on skin scrapings, acetate-tape strips, and coated brushing.
Treatment: Mites can live for several months without food, so destocking a shed for a short time will not eliminate the problem. Spray birds and sheds with insecticide, making sure that all cracks in buildings are penetrated. Nesting material should be removed and burnt or buried. Treatment must be repeated at seven days to break the life cycle. Scaly leg of chickens can be treated by smearing Vaseline jelly with insecticide or dipping the leg in paraffin (kerosene) and then gently brushing the leg. Paraffin must not be allowed to touch the skin or feathers.

CAUTION ON THE USE OF INSECTICIDES

Birds, particularly ducks, are susceptible to poisoning by most insecticides if they are used too frequently or in high concentrations. The directions on the container should be followed carefully. Do not use insecticides that are not intended for poultry. Some insecticides suitable for treating sheds and yards are not suitable for treating the birds themselves, and birds should not even be in the shed when they are being applied. Even if insecticides do not seem to affect the birds, they may be absorbed and appear in the eggs or meat, making these products unsuitable for human consumption. This can happen from treatment of the birds themselves or from exposure to a treated shed or yard. If exposure to insecticides is temporary the effect will wear off, so eggs and meat become safe again after a ‘withholding period’. The withholding period for a particular insecticide is stated on the label and must be observed.

Egg Drop Syndrome

Other names: egg drop, egg drop syndrome 76, EDS-76.

Clinical signs and lesions: There are no reliable signs other than the effects on egg production and egg quality. Healthy-appearing hens start laying thin-shelled and shell-less eggs. Once established in a flock, the condition results in decreased egg production. Transient diarrhea and dullness occur prior to eggshell changes. Fertility and hatchability are not affected.

Differential diagnosis: Similar egg production impacts can be caused by failures in husbandry, such as a lack of food or water, or infectious diseases such as infectious bronchitis, avian influenza, or Newcastle disease.

Cause, transmission, and epidemiology: Egg drop syndrome is caused by an adenovirus. It is believed that the syndrome was first introduced into chickens from contaminated vaccines. Vertical transmission occurs from infected breeders to chicks. Newly hatched chicks excrete the virus in their feces.

Diagnosis: EDS 76 is definitively diagnosed by the isolation and identification of the causative adenovirus from birds with the typical clinical syndrome. Diagnosis can also be made serologically using a hemagglutination inhibition test.

Treatment: There is no successful treatment of infected birds. Induced molting will restore egg production.

Prevention: Prevention involves a good biosecurity program.

Recovery: The virus causing EDS 76 is very stable in the environment and is therefore difficult to eradicate once a premises has housed infected birds. Vaccination of subsequently placed birds will prevent the occurrence of disease.
Endoparasites: *Acuaria hamulosa* (nematode)

**Other names:** Gizzard worm. Sometimes placed in the genus *Cheilospirura*.

**Clinical signs and lesions:** Clinical symptoms are mild and characterized by emaciation, weakness, droopiness, and anemia. The worm lives underneath the horny lining of the gizzard, where it produces soft nodules in the musculature, which weakens the organ.

**Cause, transmission, and epidemiology:** This worm is a nematode in the family Acuariidae. It has been reported in Africa (Nigeria, Ethiopia, Tanzania, Kenya, Uganda, and Zimbabwe), the Americas, Europe, and Asia. The male worms are 10–14 mm and the females are 16–29 mm long. They have long cuticular cords, which are irregular and wavy, running 2/3 of the way down the body. The adult worms are found embedded in nodules or abscesses under the keratinized layer of the gizzard.

This species utilizes grasshoppers, beetles, sandhoppers, and weevils as intermediate hosts.

**Diagnosis:** Presence of embryonated eggs in feces is indicative, but these needs to be differentiated from other spirurid eggs. Confirmatory diagnosis is at postmortem.

**Treatment:** There is no satisfactory treatment.

**Prevention:** The best method of prevention is raising the birds on wire (off the ground).

**Recovery:** Once infested birds have shed parasite eggs into the environment, viable eggs will remain until they are removed, which is not feasible. So, after a flock has been infested, new birds cannot be raised on the ground without the risk of infestation. A wire or cement flooring must be introduced to remove or reduce risk to new flocks.

Endoparasites: *Amoabotaenia sphenoides* (cestode)

**Clinical signs and lesions:** This worm occurs in the small intestine (duodenum) of the chicken, but it is not associated with disease in poultry.

**Cause, transmission, and epidemiology:** It has an indirect life cycle, and earthworms serve as intermediate hosts. It is cosmopolitan in distribution.

Endoparasites: *Ascaridia galli* (nematode)

**Clinical signs and lesions:** Light to medium infestations may not produce clinical signs; however, heavy infestations may cause diarrhea, intestinal occlusion, intussusceptions, emaciation, anemia, and death. There is reduced egg production, and birds appear unthrifty. Lesions caused by this worm are cattarhal or hemorrhagic enteritis. This parasite has been implicated in some cases of egg yolk peritonitis.

**Differential diagnosis:** *Hartertia gallinarum*, which has been reported from Asia and southern and western Africa.
Poultry Disease Handbook for Africa

Cause, transmission, and epidemiology: *Ascaridia galli* is a nematode parasite that causes ascariosis in chickens, guinea fowl, turkeys, geese, and other wild birds worldwide. It lives in the small intestine. Adult worms are semi-transparent; males measure 50-76 mm, while female worms are 72-16 mm long. The oral opening has 3 large lips, and the esophagus has no posterior bulb.

This worm has been reported worldwide. It has a direct life cycle, and earthworms may act as transport hosts.

Diagnosis: Diagnosis is through finding eggs in feces, or worms during postmortem examination.

Treatment: Piperazines work well.

Prevention: Separate young birds from old birds when kept in enclosures. Moisture levels and ventilation should be monitored.

Recovery: Once infested birds have shed parasite eggs into the environment, viable eggs will remain until they are removed, which is not feasible. Therefore, after a flock has been infested, new birds cannot be raised on the ground without the risk of infestation. Wire or cement flooring must be introduced to remove or reduce risk to new flocks.

---

Endoparasites: *Capillaria species* (nematode)

Clinical signs and lesions: The birds appear weak and emaciated. *Capillaria contorta* and *C. annulata* cause catarrhal inflammation, and thickening of the crop and esophagus. *C. caudinflata*, *C. bursata*, *C. obsignata* and *C. anatis* are associated with hemorrhagic enteritis and bloody diarrhea.

Cause, transmission, and epidemiology: These are small, hair-like worms found in the digestive tract. *Capillaria* species are cosmopolitan. They include: *Capillaria annulata*, *C. contorta*, *C. caudinflata*, *C. bursata*, *C. obsignata*, and *C. anatis*. *Capillaria caudinflata* and *C. annulata* are found in the crop and esophagus. *Capillaria caudinflata*, *C. obsignata*, *C. bursata*, and *C. anatis* are found in the intestine.

*Capillaria caudinflata* and *C. annulata* utilize earthworms as the intermediate hosts. *Capillaria obsignata*, *C. anatis* have a direct life cycle. *Capillaria contorta* may have a direct or an indirect life cycle.

Diagnosis: Diagnosis is through detection of eggs in feces and worms during postmortem examination.

Treatment: Treatment is with coumaphos and febendazoles.

Prevention: Control and prevention is by separation of birds from possible transport and intermediate hosts, and effective cleaning of poultry houses and premises.

Recovery: Once infested birds have shed parasite eggs into the environment, viable eggs will remain until they are removed, which is not feasible. Therefore, after a flock has been infested, new birds cannot be raised on the ground without the risk of infestation. Wire or cement flooring must be introduced to remove or reduce risk to new flocks.
Endoparasites: *Choanotaenia infindibulum* (cestode)

**Clinical signs and lesions:** This worm occurs in the upper small intestine of chickens and turkeys, and has been associated with weight loss in affected birds.

**Cause, transmission, and epidemiology:** *Choanotaenia infindibulum* is distributed worldwide. It has an indirect life cycle, with houseflies and beetles acting as the intermediate hosts.

Endoparasites: *Davainea proglottina* (cestode)

**Clinical signs and lesions:** Clinical signs associated with this flatworm parasite are retarded growth, weakness, diarrhea, and nervous disorders characterized by partial or incomplete paralysis. It is the most pathogenic cestode in poultry, and is associated with nodules on the mucosa of the intestines and haemorrhagic enteritis in heavy infestations.

**Cause, transmission, and epidemiology:** This worm belongs to the family Davaineidae. It occurs in the duodenal loop, and is found in domestic fowl and other gallinaceous birds in most parts of the world. It has an indirect life cycle, with snails acting as the intermediate hosts.

**Diagnosis:** Diagnosis is made by accurate identification of the parasite during necropsy and/or by demonstration of proglottides in feces of birds.

**Treatment:** Niclosamide is an effective for treatment of this infestation.

**Prevention:** Improvement of sanitary practices and application of approved pesticides to the soil or litter in the premises will interrupt the parasite life cycle by destroying the intermediate host. Separate birds according to species and age groups where possible.

**Recovery:** Once infested birds have shed parasite eggs into the environment, viable eggs will remain until they are removed, which is not feasible. Therefore, after a flock has been infested, new birds cannot be raised on the ground without the risk of infestation. Wire or cement flooring must be introduced to remove or reduce risk to new flocks.

Endoparasites: *Gongylonema ingluvicola* (nematode)

**Clinical signs and lesions:** This nematode parasite creates convoluted tracts in the crop wall. It causes a mild chronic inflammatory reaction with flattening, compression, and cornification of the epithelium.

**Cause, transmission, and epidemiology:** This nematode belongs to the family Gongylonematidae. It is a thread-like worm. Adults are normally found embedded in the epithelium of the crop, esophagus, and sometimes the proventriculus. Male worms are 17-20 mm and females are 32-55 mm long. It is found in chickens, turkeys, partridges, and quail. It has been reported in many parts of the world and Africa (central, eastern and northern).

The parasite has an indirect life cycle and utilizes beetles and cockroaches as the intermediate hosts.
Diagnosis: Definitive diagnosis can be arrived at during postmortem examination. The parasite has cuticular thickenings, which are oval to round on the anterior aspect. The tail of the male worm has a number of papillae and spicules. The left spicule is slender and longer than the right one.

Treatment: There is no treatment for this infection.

Recovery: Once infested birds have shed parasite eggs into the environment, viable eggs will remain until they are removed, which is not feasible. Therefore, after a flock has been infested, new birds cannot be raised on the ground without the risk of infestation. Wire or cement flooring must be introduced to remove or reduce risk to new flocks.

Endoparasites: Heterakis species (nematode)

Clinical signs and lesions: Heterakis gallinarum occurs in the caeca of chickens, guinea fowl, turkeys, ducks, and geese. These are small, white worms with 3 lips in the mouth and the esophageal bulb with a valvular apparatus. Their clinical effects are minimal, but heavy infections do cause thickening of the caecal mucosa, petechial haemorrhages, and hepatic granulomas. This parasite is also the carrier of Histomonas meleagridis, the causal agent of blackhead.

Heterakis isolonche occurs in the caecum of chickens, quail, and pheasants. It causes diarrhea, wasting, emaciation and death. Pathological lesions include confluent nodular (warty) thickening of the caecal wall.

Differential diagnosis: Ascaridia galli and other nematode worms. Subulura species (S. brumpti, S. minetti, S. differens, S. strongylina, and S. suctoria) are important as a differential diagnosis, but are not known to cause lesions.

Cause, transmission, and epidemiology: This genus belongs to the family Heterakidae. Heterakis gallinarum and Heterakis isolonche are important parasites of poultry in Africa. Other species in the genus are Heterakis dispar, which has been reported in ducks and geese, and Heterakis brevispiculum, found in chickens and guinea fowl.

Heterakis isolonche has a direct life cycle, but earthworms may serve as a transport host.

Diagnosis: Diagnosis is made by finding eggs in feces. These eggs must be differentiated with those of A. galli and other related worms. Definitive diagnosis is arrived at postmortem by the presence of the worms.

Treatment: Treatment is with phenothiazine.

Prevention: This infection can be minimized by strict sanitation in poultry houses.

Recovery: Once infested birds have shed parasite eggs into the environment, viable eggs will remain until they are removed, which is not feasible. Therefore, after a flock has been infested, new birds cannot be raised on the ground without the risk of infestation. Wire or cement flooring must be introduced to remove or reduce risk to new flocks.
**Endoparasites: *Hymenolepis* species (cestode)**

*Clinical signs and lesions:* These tapeworms are thread-like and inhabit the small intestine, where they are associated with catarrhal enteritis and diarrhea in birds.

*Cause, transmission, and epidemiology:* This genus contains *Hymenolepis carioca*, *H. cantaniana*, *H. lanceolata* and *H. nyrocæ*.

*Hymenolepis* species have been reported in chickens in Africa and the United States. They have an indirect life cycle with dung beetles acting as the intermediate hosts.

**Endoparasites: Protozoans**

*Clinical signs and lesions:* Some protozoans produce coccidiosis, which can cause decreased growth, diarrhea, and high mortality in poultry, or they can be nearly asymptomatic in presentation. Coagulative necrosis, and mucoid and hemorrhagic enteritis also occur.

*Differential diagnosis:* Necrotic enteritis, ulcerative enteritis, blackhead.

*Cause, transmission, and epidemiology:* The main protozoan parasites in poultry are in the genera *Eimeria*, *Cryptosporidia*, *Histomonas*, *Trichomonas*, *Tetratrichomonas*, *Entamoeba*, and *Endolimax*. There are also tissue protozoan parasites in the genera *Sarcocystis*, *Toxoplasma*, and *Neospora*. Of all these, coccidial and *Histomonas* parasites are the most important, especially in commercial birds. The most pathogenic *Eimeria* species are *E. tenella*, *E. necatrix*, and *E. brunetti*. *Eimeria cervulina* and *E. maxima* are less pathogenic.

These parasites are cosmopolitan, and all are of little importance in free-ranging family poultry with low density. However, guinea fowl keets can suffer acute disease and high mortality from histomoniasis (blackhead), which can be predisposed by coccidiosis. While older fowl can become sick and emaciated for some time, mortality rates are low as they are more resistant to the protozoan. Losses are usually low in chickens and turkeys.

*Diagnosis:* Diagnosis is by clinical signs and pathological lesions, and demonstration of various coccidial stages and oocysts in fecal materials or microscopic sections.

*Treatment:* Several anticoccidial compounds are effective: amprolium, sulfadimethoxine, sulfaquinoxaline, and sulfamethazine.

*Prevention:* Coccidiostats can be used to prevent disease. Birds that are infected and survive will develop immunity. Early exposure to low doses of coccidians can be effective, as can vaccination.

*Recovery:* Preventing fecal-oral transmission cycles by placing birds on wire will usually prevent the recurrence of clinical disease.
Endoparasites: *Raillietina species* (cestode)

*Clinical signs and lesions:* *Raillietina tetragona* is found buried in the intestinal mucosa and infestations are associated with weight loss and decreased egg production. *R. echinobothrida* is associated with catarrhal enteritis, nodular formation, and granulomas, and causes nodular disease. *R. cesticillus* causes emaciation and degeneration of intestinal villi.

*Cause, transmission, and epidemiology:* Species in this genus that have been reported in free ranging poultry include *R. tetragona*, *R. echinobothrida*, and *R. cesticillus*. These worms are cosmopolitan.

*R. tetragona* occurs in the posterior half of the small intestine, and has been reported in chickens, pigeons, and pea fowl. *R. echinobothrida* occurs in the small intestine of chickens and turkeys. *R. cesticillus* occurs in the small intestine of chickens, guinea fowl, and turkeys. All have an indirect life cycle that utilizes ants, beetles, and flies as the intermediate hosts.

*Diagnosis:* Diagnosis is made by accurate identification of the parasite during necropsy and by identifying proglottides in feces.

*Treatment:* Broad spectrum benzimidazoles are effective for treatment of infestations of this tapeworm.

*Prevention:* Improve sanitary practices and apply approved insecticides to the soil or litter on the premises. This interrupts the parasite’s life cycle by destroying the intermediate hosts. Separate birds according to species and age groups.

Endoparasites: *Strongyloides avium* (nematode)

*Cause, transmission, and epidemiology:* This genus belongs to the family Strongyloidae. The worms inhabit the small intestine and the cecum of fowl, turkeys, and wild birds. It is reported in most parts of the world including Africa. *Strongyloides avium* has a direct life cycle. Only the female worms are parasitic. They are 2.2 mm long, and associated with thickening of the walls of the cecum.

Endoparasites: *Syngamus trachea* (nematode)

*Other names:* Gapeworm, red worm, forked worm.

*Clinical signs and lesions:* *Syngamus trachea* causes gapeworm disease, which is characterized by dyspnoea and asphyxia, anemia, mucus production in the airways, and progressive emaciation. The bird may cough and perform gaping movements when the worms clog and obstruct the airways. Death may occur due to asphyxiation. Worms may be seen in the posterior trachea.

*Cause, transmission, and epidemiology:* *Syngamus trachea* is a nematode in the family Syngamidae. This worm is cosmopolitan and has been reported in Africa. It occurs in chickens, turkeys, geese, quail, and various wild birds. It is bright red in color, and both sexes are in permanent procreative conjunction. When the female gapeworm lays her eggs in the trachea of an infected bird, the eggs are coughed up, swallowed, and then defecated. Birds become infected when they consume eggs found in the feces or an intermediate host such earthworms, slugs, or snails.
Cyathostoma bronchialis is a gapeworm of geese and turkeys.

**Diagnosis:** Diagnosis is based on clinical signs, characteristic eggs in the feces, and finding the worms in the airways at postmortem.

**Treatment:** Albendazoles can be used to cure infection. An appropriate disinfectant must also be used to treat infected pens.

**Prevention:** Keep pens dry. Turkeys should not be kept in the same pens with chickens.

### Endoparasites: *Tetrameres* species (nematode)

**Other names:** Globular stomach worms.

**Clinical signs and lesions:** *Tetrameres* worms are associated with edema, thickening, and obstruction of the proventriculus in infested birds. Microscopically, they cause dilatation of proventricular glands, and compression and necrosis of glandular epithelial cells.

**Cause, transmission, and epidemiology:** This nematode worm has been reported in Africa and North America. The two species reported in Africa to date are *Tetrameres americana* (Botswana, Ethiopia, Kenya, Nigeria, Tanzania, and Zimbabwe) occurring in chickens and turkeys, and *T. fissispina* (Tanzania, Ghana, and Kenya) occurring in chickens, ducks, turkeys, and pigeons.

The female worm is spherical in shape, blood-red in color, measures 3.5-4.5 mm by 3 mm long, and lies embedded in the proventriculus gland of infected birds. The male is slender, measuring 5-5.5 mm long and 16-33 µm wide, armed with four rows of cuticular spines, and found free in the lumen of the proventriculus. They may follow females into the gland temporarily for copulation.

These parasites have indirect lifecycles. *Tetrameres americana* uses grasshoppers and cockroaches as the intermediate hosts, and *T. fissispina* uses earthworms, grasshoppers, amphipods, and cockroaches.

**Diagnosis:** Definitive diagnosis is reached at postmortem through identification of the worm.

### Endoparasites: Trematodes

There are many trematodes (flukes) reported in birds, represented by the genera *Brachylaemus*, *Echinostoma*, *Echinoparyphlum*, *Hypodraeum*, *Notocotylus*, *Cattropis*, and *Postharmostomum*. *Prosthogonimus pellucidus* has been reported in Kenya, and *Brachylaemus commutatus* from Uganda. *Prosthogonimus pellucidus* occurs worldwide in fowls and ducks. *Prosthogonimus macrorchis* is reported in poultry in North America. *Prosthogonimus ovatus* has been found in geese in Africa, Europe, Asia, and North and South America.

These flukes occur in the bursa of Fabricius, oviduct, cloaca, and rectum. Adult worms measure 8-9 mm long and 4-5 mm wide, and are broader at the posterior end than the anterior end.
Birds infected by *Prosthogonimus* species have a tendency to sit on the nest, have a milky discharge from the cloaca, and lay eggs with soft or no shells. In chronic infestations the birds have peritonitis.

**Endoparasites: *Trichostrongylus tenuis* (nematode)**

**Clinical signs and lesions:** This species is associated with severe weight loss and anemia, and a thickened and congested caecal wall.

**Cause, transmission, and epidemiology:** *Trichostrongylus tenuis* is worldwide in distribution and occurs in the caecum and intestines of chickens, turkeys, ducks, and game birds. Male worms are 5.5–9 mm, while females are 6.5–11 mm long. They have a direct life cycle.

**Equine Encephalitis Viral Infection**

**Other names:** Alphavirus infection.

**Clinical signs and lesions:** Infected birds are often transiently infected and may show no clinical signs. When present, clinical signs in sick flocks involve the central nervous system, and include ataxia, paresis, paralysis, inability to stand or to hold up the neck, circling, and tremors.

Typically there are no lesions that are grossly evident. Microscopic lesions occur in the brain of most clinically ill birds, but are not specific for the encephalitides.

**Differential diagnosis:** Equine encephalitis must be differentiated from diseases that cause neurologic symptoms in poultry, including Newcastle disease (neurologic form), Marek's disease, avian encephalomyelitis, vitamin E deficiency, avian influenza, and botulism.

**Cause, transmission, and epidemiology:** Equine encephalitis viral infection is an acute disease caused by several alphaviruses in the family Togaviridae. Eastern equine encephalitis (EEE) and Western equine encephalitis (WEE) viruses are among a number of possible causative agents. The disease affects pheasants, chukar partridges, turkeys, ducks, pigeons, and some species of wild birds. Most outbreaks occur in captive gamebirds birds and poultry under six months of age. Morbidity and mortality rates can be very high. EEE and WEE viruses can infect humans, causing severe or fatal illness.

The viruses are transmitted mainly by mosquitoes, primarily *Culiseta melanura*. After feeding on viremic birds mosquitoes become infected with the virus, whose titer may increase within the vector. Infected mosquitoes then transmit the virus to susceptible birds while feeding on them. Because birds maintain a higher titer of virus than mammals, they serve as the primary reservoir for the disease. Biting flies such as gnats, deerflies, and horseflies may transmit the virus mechanically on their mouthparts. Transmission can also occur through cannibalism of viremic or dead birds by susceptible birds.

**Diagnosis:** In flocks with clinically ill birds, the signs are suggestive of central nervous system disease. Definitive diagnosis is made by isolating and identifying the virus. Isolation is usually via chicken embryos, laboratory mice, or tissue culture. Specific identification is usually made via virus neutralization or complement fixation tests.

**Treatment:** Treatment of sick birds is of no value.
Prevention: Protect birds against mosquitoes by the use of screens, sprays, or other mosquito control methods. In family poultry, the traditional method is by the use of fire and smoke.

Practice known methods of preventing cannibalism, including maintaining temperature controls and avoiding overcrowding. Prevent or treat ectoparasite infestations.

Recovery: There is no residual risk of infection after a case has occurred based on environmental contamination. However, if the conditions which resulted in the initial infection (presence of mosquitoes, presence of a reservoir host) are not corrected, then new birds may be infected.

### Favus

**Other names:** Dermatophytosis, dermatomycosis, ringworm.

**Clinical signs and lesions:** Favus is a skin mycotic infection rare in commercial poultry, but occasionally found in small flocks, and especially in gamebirds. Other than skin lesions, affected birds are typically healthy.

Favus lesions appear as scaly white crusting on the comb and wattles. Infection begins on unfeathered skin and can extend to the feathered portion of the skin of the head and neck, and cause feather loss. Scutula sometimes form around the bases of the feather follicles. The fungus infects the epidermis, which is thickened with degeneration, and neutrophils mixed with fungal mycelia.

**Differential diagnosis:** Other skin infections and causes of feather loss (ectoparasites and trauma).

**Cause, transmission, and epidemiology:** *Microsporum gallinae* is the primary causal agent. *Microsporum gypseum* and *Trichophyton simii* have also been implicated. The infection is contagious and is transmissible to man, as are the majority of dermatophytes that cause ringworm. Favus has been reported in chickens, turkeys, ducks, quail, and canaries, and is a primary pathogen. It spreads slowly through a flock by direct contact, or indirect contact through contaminated cages or transport coops.

**Diagnosis:** Skin scrapings placed on 10% KOH on a glass slide with a coverslip and then gently heated will show the lesion mycelium or hyphae. They can also be grown on Sabouraud dextrose agar. Histological examination of tissue stained with Gridley or other fungal stains will show characteristic hyphae.

**Treatment:** There is no approved treatment, but topical treatment with Nystatin has been effective on individual birds. Application of a 2% quaternary ammonium disinfectant, 1% tincture of iodine, or 5% formalin will often eliminate the infection.

**Prevention:** Biosecurity precautions should be implemented to avoid introducing infected birds to the flock. Transport crates and other equipment should be thoroughly decontaminated and disinfected to prevent transmission of the agent.

**Recovery:** Complete recovery requires that all individuals in a flock are cured of infection and that none of the causative agents remain in the environment. Recovery may be prolonged if treatment is incomplete or if the environment is not decontaminated.
Fowl Cholera

Other names: avian pasteurellosis, cholera, avian hemorrhagic septicemia.

Clinical signs and lesions: Fowl cholera usually strikes birds older than 6 weeks of age. In acute outbreaks, sudden mortality may be the first sign. Fever, reduced feed consumption, mucoid discharge from the mouth, ruffled feathers, diarrhea, and labored breathing may be seen. As the disease progresses, birds lose weight, may become lame from joint infections, and develop rattling noises due to exudate in air passages. When fowl cholera becomes chronic, chickens develop abscessed wattles and swollen joints and foot pads. Caseous exudate may form in the sinuses around the eyes. Turkeys may have twisted necks caused by infections of the inner ear.

Differential diagnosis: Fowl cholera must be differentiated from swollen head syndrome (metapneumovirus), mycoplasmosis, avian influenza, and Newcastle disease.

Cause, transmission, and epidemiology: Multiple means of transmission have been demonstrated. New additions to a flock and free-flying birds may transmit the causative bacteria directly. Infected premises, predators, and rodents may also be sources of infection.

Diagnosis: A presumptive diagnosis can be made based on the clinical signs of the disease and gross lesions evident on necropsy. A definitive diagnosis is based on direct identification in tissue imprints, or the isolation and identification of \textit{P. multocida} from affected birds.

Treatment: A flock can be medicated with a sulfa drug (sulfonamides, especially sulfadimethoxine, sulfadinoxalene, sulfamethazine, and sulfadioxalene), or vaccinated, or both, to stop mortality associated with an outbreak. In the United States sulfa drugs are not FDA approved for use in pullets older than 14 weeks or for commercial laying hens because of their potential toxicity to humans; sulfa drugs leave residues in meat and eggs. Other antibiotics can be used, but require higher levels and long term medication to stop the outbreak.

Prevention: On fowl cholera endemic farms, vaccination is advisable. Do not vaccinate for fowl cholera unless there is a problem on the farm. Rodent control and complete cleaning and disinfection of the premises are essential to prevent future outbreaks.

Recovery: Most flocks will recover from outbreaks of fowl cholera, although if it is not detected and treated correctly, its economic impact may be devastating. After the flock has been treated, every effort should be made to ascertain the source of the bacterial disease agent and prevent future infections. Recovery is only possible if the environment is fully depopulated and cleaned, and rodents on the premises removed before susceptible birds are reintroduced.
Fowl Pox

**Other names:** chicken pox (not to be confused with chicken pox in humans; the human disease does not affect poultry and vice versa), sore head, avian diphtheria, bird pox.

**Clinical signs and lesions:** There are two forms of fowl pox. The dry form is characterized by raised, wart-like lesions on unfeathered areas (head, legs, vent, etc.). The lesions heal in about 2 weeks. If the scab is removed before healing is complete, the surface beneath will be an open bleeding wound.

Unthriftiness and retarded growth are typical symptoms of fowl pox, especially when the lesions cover the eyes or mouth. In laying hens, infection results in a transient decline in egg production.

In the wet form there are canker-like lesions in the mouth, pharynx, larynx, and trachea. The wet form may cause respiratory distress by obstructing upper air passages. Chickens may be affected with either or both forms of fowl pox at one time.

**Differential diagnosis:** Vitamin A deficiency, favus, stick tight fleas

**Cause, transmission, and epidemiology:** Fowl pox is a viral disease affecting most species of poultry. Chickens, turkeys, pheasants, quail, ducks, psittacines, and ratites of all ages (except newly-hatched chicks) are susceptible. The disease is transmitted by several species of mosquitoes, or by direct contact between infected and susceptible birds. Virus-containing scabs also can be sloughed from affected birds and serve as a source of infection. The virus can enter the blood through the eye, respiratory tract, or open skin wounds.

Mosquitoes are the primary reservoir host and transmitters of fowl pox on poultry ranges. They become infected by feeding on viremic birds. There is some evidence that mosquitoes remain infective for life. Often mosquitoes over-winter in poultry houses, so outbreaks can occur during winter and early spring.

**Diagnosis:** Usually diagnosed by clinical signs, but lesion material containing fowl pox particles will produce pocks on the dropped chorioallantoic membrane of embryonated chicken eggs. Intracytoplasmic inclusion bodies may be seen in stained sections or in scrapings of the lesions in chickens, but may not be visible in turkeys.

**Treatment:** No treatment is available. However, fowl pox is relatively slow-spreading. Thus, it is possible to vaccinate to stop an outbreak.

**Prevention:** In poultry confined to houses, fowl pox outbreaks can be controlled by spraying to kill mosquitoes. However, if fowl pox is endemic in the area, vaccination is recommended. Do not vaccinate unless the disease becomes a problem on a farm or in the area. Chickens may be vaccinated at 4-6 weeks of age using the wing web-stick method, and turkeys older than 8 weeks by the thigh-stick method.

**Recovery:** Most individuals with fowl pox will recover and will clear the virus. Recovered birds are not reservoirs of infection. Flocks can recover from infection, but the environment must be cleaned and vectors controlled before new birds are introduced.
Uric acid is produced in the liver and is the end product of nitrogen metabolism in birds. Birds can develop gout secondary to an accumulation of urates. Gout is not a disease entity, but a clinical sign of severe renal dysfunction that causes hyperuricemia and accumulation of urates in tissues of birds. There are two different syndromes that differ in etiology, morphology, and pathogenesis. The two forms are visceral gout and articular gout.

A. Visceral Gout:

Clinical signs and lesions: The urate deposits appear as a white chalky coating. Within the viscera, they are observed microscopically as blue or pink amorphous material or feathery crystals, or basophilic spherical masses in tissues.

Cause, transmission, and epidemiology: The condition is due to a failure of the urinary excretion of uric acid. This can be as a result of:

- Dehydration – most common cause
- Ureters obstruction
- Renal damage
- Vitamin A deficiency
- Urolithiasis
- Treatment with sodium bicarbonate

Visceral gout generally occurs because of hyperuricemia and subsequent precipitation and crystallization of urates. Other causes are mycotoxins such as oosporein, and renal cryptosporidiosis (in geese). Mechanisms of crystal precipitation in some sites are unknown.

Diagnosis: This form is characterized by precipitation of urates in the kidneys, and serous surfaces of the liver, heart, mesenteries, air sacs, or peritoneum. In severe cases, surfaces of muscles and synovial sheaths of tendons and joints are affected. Precipitation of urates can occur within the liver, spleen, and other organs.

Treatment: Correcting the cause of the renal damage or ureters obstruction will prevent other birds from developing gout.

Prevention: Visceral gout is prevented by feeding a correctly balanced diet and providing adequate water for chickens.

Recovery: Individual affected birds will not recover, but once the cause of the condition is corrected, there will not be an increased residual risk to new birds on the premises.

B. Articular Gout

Clinical signs and lesions: Affected birds have shifting lameness and an inability to bend the toes. The disease is characterized by tophi - deposits of urates around joints, especially the feet. Joints are enlarged and hot, and feet are deformed. In chronic cases, urate precipitation is found in the comb, wattles, trachea, and other areas.
**Differential diagnosis:** This form of gout must be differentiated from other diseases causing joint and skin swellings and abscesses, such as bumble foot, lymphoid leukosis (osteopetrosis), infectious tenosynovitis, *Mycoplasma synoviae*, and staphylococcus.

**Cause, transmission, and epidemiology:** This form is generally restricted to individual birds, and may be due to genetic defects in metabolism of uric acid. It may be a result of feeding high protein diets, which result in excess uric acid production. Affected chickens have a defect in kidney tubular secretion of uric acid. Articular gout is more common in males than in females, potentially due to a lower protein requirement for roosters.

**Diagnosis:** On opening the joints, periarticular tissue appears white and chalky due to urate deposition, and semifluid deposits of urates are seen.

**Treatment:** There is no treatment for this condition, although providing a lower protein diet may be helpful.

**Prevention:** Provide a lower protein diet, especially for males.

**Recovery:** This is a sporadic problem of little economic importance in poultry. Individual birds will not recover.

---

**Hemoparasites (blood parasites)**

**GENERAL INFORMATION**

**Clinical signs:** A heavy infestation of hemoparasites can cause anemia and death by invading blood cells, especially erythrocytes, which consequently are destroyed by the bird’s immune system.

**Cause, transmission, and epidemiology:** Hemoparasites are fairly common in many birds, especially wild birds. Hemoparasites are also found in poultry, mainly in tropical areas, and include species in the following genera: *Plasmodium* spp., *Leucocytozoon* spp., *Haemoproteus* spp., *Aegyptinella* spp., *Eperythrozoon* spp., and *Trypanosoma* spp. Microfilaria of nematodes belonging to the suborder Filariata can also be blood pathogens; over 10 species of these are of pathogenic and economic importance. Transmission is by arthropod vectors, including mosquitoes and biting midges as well as other flies, and the poultry soft tick (*Argas persicus*). Unlike semi-wild and wild birds whose blood parasites have been investigated, information on haemoparasitic infections in domestic family chickens in Africa is limited.

**Diagnosis:** Preparation of blood smears: Thin blood films are prepared from fresh blood, or unclotted (EDTA or heparin treated) blood. Blood films are air-dried within 5–10 sec of preparation, fixed in methanol for 5 minutes, stained with Giemsa (10%) for 10 to 15 minutes, washed with tap water, blotted, coverslipped, and examined under a light microscope for hemoparasites. Examination of blood smears: Blood films are examined for 10–15 minutes at low magnification (X10-X40), and then at least 20 fields are studied at high magnification (X100).

**Treatment:** Treatment is usually not cost effective, but can be done with anti-malarial compounds.

**Prevention:** Attempts at prevention are usually not sustainable, since it is difficult to adequately control the arthropod vectors involved in transmission of these parasites.
Poultry Disease Handbook for Africa

Recuperación: Los hemoparasitos suelen reaparecer en la aves donde ocurrieron casos previos. La presencia de los vectores y huéspedes de reserva para los hemoparasitos (aves silvestres) son usualmente parte del ecología de un lugar y, por lo tanto, no pueden ser eliminados, por lo que la enfermedad clínica reaparecerá si las aves inmunológicamente no son colocadas en los mismos sitios.

ESPECIES INFORMACIÓN

Hemoparasitos: *Plasmodium* species

El mal de las aves tiene una distribución mundial y es de considerable significado económico para la avicultura. *Plasmodium gallinaceum* y *P. juxtanucleare* son los dos principales tipos de parásitos de malaria encontrados en pollos y pavos. *Plasmodium gallinaceum* se encuentra en Asia y África, mientras que *P. juxtanucleare* aparece en América del Sur, África y Asia.

**Síntomas y lesiones:** *Plasmodium gallinaceum*, *P. juxtanucleare* y *P. durae* pueden causar hasta el 90% de mortalidad en aves. Provocan emaciación progresiva, anemia, y aumento del tamaño del hígado y la médula en aves afectadas. La parálisis puede ser observada donde hay masas de formas eritrocíticas en células endoteliales del cerebro, y la muerte ocurre en casos no tratados.

Gross lesions include hepatomegally and splenomegally with subcutaneous, pulmonary, and epicardial edema. Erythrocytic schizogony is the most striking microscopic lesion. This lesion is most evident in the lungs, spleen, and liver. Acute interstitial pneumonia and diffuse reticulo-endothelial hyperplasia in the spleen and other organs are present.

**Causa, ciclo vital, transmisión y epidemiología:** *Plasmodium* spp. han sido reportados en Nigeria y Kenia. Las aves se infectan con *Plasmodium* cuando un mosquito infectado muerde y los sporozoitos se transfieren desde las glándulas saliva del mosquito al torrente sanguíneo. Los parásitos enfrentan schizogony in macrofagos y fibroblastos y luego las células hepáticas, produciendo merozoitos. Estos merozoitos entran eritrocíticos, multiplican por schizogony and finally form gametocytes, which are ingested by mosquitoes during feeding. Both gametocytes and schizonts of *P. gallinaceum* can be round, oval, irregular, or slightly elongated in shape. The nucleus of host cells is displaced by the parasite, and host cells are distorted during infection.

In *Plasmodium* infections, merozoites or ring forms of the organism are usually apparent within eritrocíticos. Los anillos pueden ser único o múltiple. Micrógametocitos y macrogametocitos también formar eritrocíticos, but are observed infrequently. *Plasmodium* produce an insoluble pigment called hemozoin. This pigment is derived from the digestion of hemoglobina found within the host's eritrocíticos and appears as refractile, yellow to brown granules within the host's eritrocíticos.

**Diagnóstico:** Este se basa en las lesiones patológicas características causadas por *Plasmodium* infección. Evaluación de sangre y monitoreo de los conteos de células de sangre blancos para la leucocitosis linfocítica son considerados para ser métodos confiables de diagnóstico ante-mortem.
Hemoparasites: Leucocytozoon species

**Clinical signs:** Leucocytozoon caulleryi is the most virulent species in this genus. Infected chickens frequently show signs of anorexia, thickened oral discharge, ataxia, anemia, and have difficulty breathing. They frequently die because of hemorrhages resulting from the rupture of megalomeronts that may develop in all organs and tissues. In addition, birds may be susceptible to secondary infection that may increase mortality.

Splenomegally, hepatomegally, and anemia are the most prominent gross lesions. Histologic sections show megaloschizonts in vascular endothelium of the brain. Smaller schizonts are seen in hepatic Kupffer cells.

**Cause, life cycle, transmission, and epidemiology:** There are two main species of Leucocytozoon commonly found in chickens: L. caulleryi and L. sabrazesi. Other frequently encountered species include L. smithi (turkeys), L. anatis (ducks), L. anseris (geese), L. neavei (guinea fowl), and L. andrewsi (chickens). Leucocytozoon species are most easily distinguished because of their large size and football-like distortion of infected cells, causing characteristic pointed ends. These parasites may infect erythrocytes or leukocytes. Leucocytozoon sabrazesi has been reported in Zimbabwe, while L. caulleryi has been reported in Nigeria and Kenya. Leucocytozoon schoutedeni (a new species) has been reported from chickens in Uganda and Cameroon.

Leucocytozoon gametocytes are found in erythroblasts and mononuclear leukocytes as ovoid (10 by 15 microns) or elongated (24 by 4 microns) forms. The host cells with elongated gametocytes become spindle shaped, with nuclei appearing as thin bands beside the parasite.

The vectors of Leucocytozoon spp. are biting midges (Culicoides spp.) and black flies (Simuliidae spp.). After transmission to the birds, the sporozoites develop into schizonts. The schizogony takes place in the brain, liver, spleen, lungs and many other organs. Merozoites are then released and may enter a new cycle, or may enter erythrocytes or erythroblasts to develop into gametocytes. The gametocytes are only found in erythrocytes. The parasitic organism lies next to the host cell nucleus and is round in form. The zygote elongates into an ookinete that passes through the intestinal wall to form oocysts under the basal lamina. In the oocysts, sporozoites are formed and introduced into new hosts. Infections occur frequently when numbers of Culicoides spp. are abundant.

**Diagnosis:** Diagnosis is based on the appearance of pathological lesions and the evaluation of blood smears to demonstrate the parasite in infected cells.

**Control and treatment:** Prevention of leucocytozoanosis is usually directed towards control of black flies or midge populations. Screening of susceptible birds has been carried out in some instances. No effective treatment is known.

Hemoparasites: Haemoproteus species

**Clinical signs:** Infections with most Haemoproteus spp. do not result in significant clinical signs of disease. Experimental infection of turkeys with Haemoproteus meleagridis (H. meleagridis) resulted in lameness, diarrhea, depression, emaciation, anorexia and occasional anemia. Muscovy ducks infected with H. nettionis suffered lameness, dyspnea, and sudden death. Pigeons infected with H. columbae had enlarged gizzards. In other avian species, anemia, anorexia, and depression have been reported occasionally, but
Haemoproteus generally is considered non-pathogenic in most species. Although generally the case, some hemoproteozoa can cause significant mortality in a narrow species range, like *H. lophortyx* in bobwhite quail. Postmortem findings of infected birds include enlargement of the spleen, liver, and kidneys. These organs also may appear chocolate-brown due to hemosiderin deposition. This pigment is derived from the digestion of hemoglobin found within the host’s erythrocytes, and appears as refractile, yellow to brown granules. Cytologic imprints of these organs may reveal schizont-laden endothelial cells. The gametocytes partially encircle the erythrocyte nucleus, forming a “halter-shaped” appearance. *Haemoproteus* gametocytes often occupy over one-half of the erythrocyte cytoplasm, with little displacement of the host cell nucleus.

Some species of *Haemoproteus* will also form large, cyst-like bodies within skeletal muscles that resemble those seen with *Sarcocystis* spp. or *Leucocytozoon* spp. infections. However, these parasites may be of little importance.

**Cause, life cycle, transmission, and epidemiology:** *Haemoproteus* spp. are intracellular, protozoan, hemotropic parasites that infect the red blood cells of birds (chickens, ducks, and geese), turtles, and lizards. They are found worldwide, and are capable of infecting a variety of birds including gamebirds (Galliformes), waterfowl (Anseriformes), raptors (Accipitriformes, Falconiformes, Strigiformes), pigeons, doves (Columbiformes), and perching birds or songbirds (Passeriformes). These parasites have been reported in Nigeria and Kenya.

*Haemoproteus* is transmitted by blood-sucking insects including mosquitoes, hippoboscid flies (louse flies), and *Culicoides* species (biting midges). Successful transmission depends on the presence of the vector, and therefore infections occur more often in the warmer and wetter months of the year. The infective stage is the sporozoite, which is present in the salivary glands of the insect vector. Once the vector bites a new host, the sporozoites enter the host bloodstream and invade endothelial cells of vessels in various tissues including the lung, liver, and spleen. Within the endothelial cells, the sporozoites go through asexual reproduction to become schizonts, which then produce numerous merozoites. These merozoites penetrate the erythrocytes and mature into either female gametocytes (macrogametocytes) or male gametocytes (microgametocytes). Gametocytes are then ingested by another blood-sucking insect, in which they undergo sexual reproduction in the midgut to produce oocysts. The oocysts rupture and release numerous sporozoites that invade the salivary gland, and serve as a source of subsequent infection for another host when the insect takes its next blood meal.

**Hemoparasites: Aegyptinella species**

**Clinical signs:** *Aegyptinella pullorum* causes fever, diarrhea, anorexia, and jaundice. At postmortem there is anemia, enlargement of the spleen, and degeneration of the kidneys.

**Cause, life cycle, transmission, and epidemiology:** The two species of *Aegyptinella*, *A. pullorum* and *A. mushkovskii*, occur in chickens, turkey, ducks, geese, and other birds in Africa, Asia, and southern Europe. They are transmitted by the poultry tick *Argas persicus*, and appear as small (0.5 to 1.0 microns), round to oval bodies within the erythrocytes. *Aegyptinella pullorum* has been reported from Zimbabwe and Ghana.

The developmental cycle of *Aegyptinella* in the avian host consists of the formation of initial bodies, developmental forms, and marginal bodies. Following feeding by an adult tick on an infected fowl, 25 days or more is required before the organism is transmissible to another bird.
Hemoparasites: Trypanosoma avium

*Cause, life cycle, transmission, and epidemiology:* *Trypanosoma avium* occurs in a wide range of birds. The most common vectors of avian trypanosomes are arthropods belonging to flies in the families Hippoboscidae, Culicidae, Ceratopogonidae, and Simuliidae. In addition, dermanyssid mites have been identified as avian trypanosome vectors. *Trypanosoma avium* has been reported in Zimbabwe, Uganda, and Cameroon.

Hemoparasites: Borrelia anserina

*Borrelia anserina* is transmitted by *Culex* mosquitoes, red mites, and the poultry tick, *Argas persicus*. Within 24-72 hours post-infection, *Borrelia anserina* spirochetes appear in the bloodstream and birds may develop high fevers. Affected birds are listless, have urates around the vent, and manifest leg weakness. This parasite has been reported in Zimbabwe.

Histomoniasis

*Other names:* blackhead, enterohepatitis

*Clinical signs and lesions:* In turkeys, the disease presents with yellow feces (due to bile excreted in urate excreta following damaged liver function), drooping wings, anorexia, closed eyes, stilted gait, and drowsiness. The head may or may not be cyanotic, the condition from which the common name “blackhead” derives. Chickens are usually asymptomatic, but there may be blood present in cecal droppings (Cecal droppings are normal and differ from fecal droppings. They are dark in color, more liquid than normal feces and are excreted once daily.), and birds may appear ill, with drooping feathers and closed eyes. Disease in guinea fowl resembles that in chickens.

Typical lesions include enlargement of the ceca and thickening of the cecal walls. The lumen of the ceca may fill with serous or hemorrhagic exudate, and peritonitis can result if the distended cecal walls rupture. Liver lesions in turkeys are typically "target" shaped, with round necrotic areas up to 1 cm in diameter which are surrounded by a raised ring.

*Differential diagnosis:* Coccidiosis may present with similar cecal lesions and may occur concurrently.

*Cause, transmission, and epidemiology:* Blackhead most commonly occurs in turkeys, but many other species may carry the causative protozoan, *Histomonas meleagridis*. Peafowl are also highlight susceptible, but chickens are usually asymptotically infected, although clinical cases have been reported.

*Histomonas meleagridis* has an indirect life cycle using earthworms as a transport host for cecal worms (*Heterakis gallinarum*), which carry the protozoan. Birds become infected by ingesting either earthworms harboring cecal worms infested with *H. meleagridis*, or the cecal worm ova containing the protozoans. During digestion, the organisms are released into the bird’s intestine. Transmission may also occur through ingestion of feces containing the organism.

*Diagnosis:* The presence of typical lesions in cecae and liver at necropsy is nearly pathognomonic. A definitive diagnosis is based on intralesional *H. meleagridis* tissue sections or by observation of the
histomonads by phase-contrast microscopy; a warmed microscope stage encourages the organisms to remain active, and therefore more easily observed.

**Treatment:** Metronidazole has been highly effective in treatment. Treatment of concurrent infestations, like coccidia, is essential for recovery.

**Prevention:** Control intermediate hosts or prevention of access of the birds to them is the best way to prevent blackhead. In commercial settings, putting birds on wire mesh or cement flooring may eliminate cases by preventing the birds access to earthworms. Chickens may harbor and asymptotically spread *H. meleagridis*, thus, raising chickens and turkeys together may increase blackhead risk in the turkeys.

**Recovery:** A full recovery to health can be made in affected flocks if risk factors are managed. However, *H. meleagridis* will not be eliminated from the environment, and if risk factors are not managed, then the disease will return.

**Histoplasmosis**

**Clinical signs and lesions:** The signs are varied and nonspecific. Histoplasmosis is a systemic fungal infection. There may be weight loss leading to emaciation together with chronic respiratory disease or infected birds may be asymptomatic. It causes disseminated granulomatous lesions in affected animals. Yellow-white variable-sized nodules may be found in the lungs, air sacs, liver, and lymphoid tissue.

**Differential diagnosis:** Other lung infections and systemic fungal infections such as aspergillosis, cryptococcosis, and dactylariosis.

**Cause, transmission, and epidemiology:** This is a chronic infectious mycotic disease of man and animals (especially dogs and cats). It has been reported in zoo birds, chickens, and turkeys.

The causative agent is a dimorphic fungus, *Histoplasma capsulatum*, which is commonly found in soil containing bird and bat manure. Infection is through aerosol inhalation of conidia produced by the mold, which contaminate the respiratory system. Lungs and lymphoid tissue are the sites of primary infection. It enters the bloodstream at the primary site and then causes widespread disease in the body.

**Diagnosis:** Diagnosis is based on clinical signs, culture of the organism, and observation of tissue granulomatous lesions with intracytoplasmic narrow-based budding yeasts, measuring 2-4 µm in diameter, in the macrophages. The fungus grows readily in culture media and soil as a white to brown mold that produces microconidia (3-4 µm, spiny and spherical) and macroconidia (8-12 µm, spherical).

**Treatment:** Treatment is symptomatic, or amphotericin B can be used to treat the fungus although in advanced cases, it will not be effective.

**Prevention:** Equipment and housing can transfer the organism so disinfection with phenol-based disinfectants can prevent spread. Alternatively, moving birds to clean facilities can be preventative.

**Recovery:** The infectious conidia are stable in the environment so, sporadic cases will recur in locations with environmental *Histoplasma* contamination.
Infectious Bronchitis

Other names: IB, bronchitis, cold.

Clinical signs and lesions: Typical respiratory signs such as coughing, sneezing, rales, wheezing, and/or gasping are present. Watery discharge from the eyes and/or nostrils, swelling of the head, and head shaking may be observed. Feed and water consumption decline. Breathing noises are more noticeable at night while the birds rest. Chicks are weak, have a loss of appetite, reduced water intake, depression, and huddle around heat sources. The virus infects many tissues of the body, including the reproductive tract. Egg-producing birds may have severe and prolonged reduction in egg laying; the few eggs laid have soft or rough shells, and the egg white becomes watery. Production recovers in 5 or 6 weeks, but at a lower rate than before infection.

Lesions outside the respiratory system include swollen kidneys, with distended ureters and tubules containing whitish uric acid crystals. Broken eggs in the abdomen may occur and result in inflammation of the peritoneum (egg yolk peritonitis).

The severity of infectious bronchitis infection is influenced by the age and immune status of the flock, environmental conditions, the virus strain, and the presence of other diseases.

Differential diagnosis: Newcastle disease.

Cause, transmission, and epidemiology: Infectious bronchitis occurs only in chickens, but affects all ages and is common on farms with high density. Infections are spread between flocks when sanitation is not followed. Downtime between flocks can prevent transmission. The causative virus belongs to the family Cornaviridae, and is easily destroyed by most disinfectants. The virus is transmitted between birds through droplets expelled by infected birds showing clinical signs of the disease. The disease spreads rapidly through a flock in this way, but may also spread through dead birds, contaminated feed bags, and through mechanical transmission by rodents. The virus can also be transmitted through eggs; however, affected embryos usually will not hatch.

A disease with similar clinical presentation, quail bronchitis, is caused by a different virus (adenovirus) and affects only quail.

Diagnosis: A tentative diagnosis is based on clinical signs and lesions and is confirmed by isolation of the virus in embryonated chicken eggs, and differentiation from ND (which shows similar signs and lesions). IBV does not agglutinate red blood cells.

Treatment: There is no specific treatment for infectious bronchitis. Antibiotics given for 3-5 days may prevent or control secondary bacterial infections. Raising the room temperature 5°F for brooding-age chickens until symptoms subside can be helpful. Young chicks can be encouraged to eat by using a warm, moist mash.

Prevention: Establish and enforce a biosecurity program. Vaccination is practiced in young chickens, but vaccine should be of the prevailing serotype on the farm and must be strictly preserved in a cold-chain.

Recovery: As IB infection tends to persist on a farm, depopulation followed by disinfection and resting of the pens is the only way to eradicate the disease. An effective vaccination program should be introduced with the arrival of the next batch of chicks.
Infectious Bursal Disease

Other names: Gumboro, IBD, infectious bursitis, infectious avian nephrosis.

Clinical signs and lesions: In affected chickens greater than 3 weeks of age, there is usually a rapid onset of the disease with a sudden drop in feed and water consumption, watery droppings leading to soiling of feathers around the vent, and vent picking. Feathers appear ruffled. Chicks are listless and sit in a hunched position. Chickens infected when less than 3 weeks of age may not develop clinical disease, but become severely and permanently immunosuppressed.

Differential diagnosis: Acute cases of IBD should be differentiated from coccidiosis, while bursal atrophy should be differentiated from Marek’s disease and Vitamin A deficiency.

Cause, transmission, and epidemiology: The virus is spread by bird-to-bird contact, as well as by contact with contaminated people and equipment. The virus is shed in bird droppings and can be spread through the air on dust particles. Dead birds are also a source of the virus and should be incinerated or composted to destroy infectious virus.

Diagnosis: A strong presumptive diagnosis can be made based on the rapid onset of morbidity and mortality and a rapid recovery in 5-7 days, which are characteristic of this disease. Gross lesions at necropsy and histopathology can confirm the etiology, as can the isolation of the causative virus. Isolation of IBVD is by CAM inoculation of chicken eggs.

Treatment: There is no specific treatment. Antibiotics, sulfonamides, and nitrofurans have little or no effect. Vitamin-electrolyte therapy is helpful. High levels of tetracyclines are contraindicated because they tie up calcium, thereby producing rickets. Surviving chicks remain unthrifty and more susceptible to secondary infections because of immunosuppression.

Prevention: Vaccines are commercially available and can be effective in preventing disease. Practice good sanitation and biosecurity.

Recovery: The virus is very stable in the environment, so it is usually not possible to prevent the spread of cases from previous flocks to new flocks. Vaccination is the key to recovery.

Infectious Coryza

Other names: Croup, cold, coryza.

Clinical signs and lesions: Swelling around the face, foul smelling, thick, opaque, sticky discharge from the nostrils and eyes, labored breathing, and rales are common clinical signs. The eyelids are irritated and may stick together. The birds may have diarrhea, and growing birds may become stunted.

Mortality from coryza is usually low, but infections can decrease egg production and increase the incidence and/or severity of other diseases. Mortality can be as high as 50%, but is usually no more than 20%. Clinical disease can last from a few days to 2-3 months, depending on the virulence of the pathogen and the existence of other infections such as mycoplasmosis.
Differential diagnosis: Clinical cases of infectious coryza can resemble swollen head syndrome (metapneumovirus), fowl pox (wet form), chlamydiosis, vitamin A deficiency, mycoplasmosis with secondary bacterial infection, or chronic fowl cholera.

Cause, transmission, and epidemiology: Infectious coryza is a bacterial disease of chickens, pheasants, and guinea fowl. The causal agent is *Hemophilus paragallinarum*, which is primarily transmitted by direct bird-to-bird contact. This can be through infected birds brought into the flock as well as from birds that recover from the disease but remain carriers of the organism, which they may shed intermittently throughout their lives. Inapparently infected adult birds added into a flock are a common source for outbreaks. Within a flock, inhalation of airborne respiratory droplets and contamination of feed and/or water are common modes of spread.

Diagnosis: A presumptive diagnosis can be made based on the epidemiology of the outbreak, clinical signs of disease, and lesions at necropsy. However, a definitive diagnosis will require isolation and identification of the bacterial disease agent.

Treatment: Water-soluble antibiotics or antibacterials can be used. Sulfadimethoxine (Albon®, Di-Methox™) is the preferred treatment. If it is not available, or not effective, sulfamethazine (Sulfa-Max®, SulfaSure™), erythromycin (Gallimycin®), or tetracycline (Aureomycin®) can be used as alternative treatments. Sulfa drugs are not approved for pullets older than 14 weeks of age or for commercial layer hens. While antibiotics can be effective in reducing clinical disease, they do not eliminate carrier birds.

Prevention: Good management and sanitation are the best ways to avoid infectious coryza. Most outbreaks occur as a result of mixing flocks. All replacement birds on "coryza-endemic" farms should be vaccinated. The vaccine (Coryza-Vac) is administered subcutaneously on the back of the neck. Each chicken should be vaccinated four times, starting at 5 weeks of age with at least 4 weeks between injections. Vaccinate again at 10 months of age and twice yearly thereafter.

Recovery: *Hemphilus paragallinarum* is easily removed from a contaminated environment with cleaning and disinfection. However, any birds on the premises must be depopulated to eliminate the bacteria since carrier birds are the major source of infection. If depopulation is not practical, then vaccination should be considered.

Infectious Laryngotracheitis

Other names: Often abbreviated as ILT or LT.

Clinical signs and lesions: Chickens and pheasants are affected by LT. Chickens over 14 weeks of age are more susceptible. The first clinical sign usually noticed is watery eyes. Affected birds remain quiet because breathing is difficult. Coughing, sneezing, and shaking of the head to dislodge exudate plugs in the trachea follow. Birds extend their head and neck to facilitate breathing (sometimes referred to as "pump handle respiration"). Inhalation produces a wheezing and gurgling sound. Blood-tinged exudates and serum clots are expelled from the trachea of affected birds. In addition to coughing, birds may gasp with loud sounds and wheeze when they shake their heads to try to expel bloody mucus exudates from their trachea (windpipe) and nostrils. Many birds die from asphyxiation when there is a blockage of the trachea. Egg production is reduced. Although morbidity is high, mortality rates are usually low.
Lesions are similar to those for other viral respiratory diseases: tracheae are inflamed, showing excessive mucus content or blood and congestion of the tracheal lining; lungs may contain excess blood or fluid; air sacs are often opaque and thickened. Inflammation of the mucous layer of the respiratory tract may progress to a false membrane made of dead tissue, with caseous material in the trachea which may block the passage and cause suffocation.

**Differential diagnosis:** ILT must be differentiated from other viral respiratory infections such as Newcastle disease and avian influenza. Mild cases of ILT may also be confused with wet pox, infectious bronchitis, or mycoplasmosis.

**Cause, transmission, and epidemiology:** The causative agent of this acute disease of chickens is a member of the Herpesviridae. It is destroyed by most disinfectants, but can persist on a premises for up to 120 days. The many strains of this virus are immunologically similar, although they vary in their ability to cause disease.

The virus spreads by inhalation of droplets within a flock, but does so less rapidly than other viruses. It can also be spread through fomites – contaminated objects found in the environment of the birds. Birds that have recovered from ILT, or that have been vaccinated, may be carriers for long periods of time.

**Diagnosis:** The signs and lesions of ILT are strongly suggestive. Tentative diagnosis can be confirmed by examining sections of the trachea microscopically for inclusion bodies in the nuclei of the cells of tracheal lining. Typically, rafts of cells are seen in the tracheal lumen leaving an exposed submucosa. More sophisticated techniques are available to confirm the diagnosis, such as the fluorescent antibody technique or PCR.

**Treatment:** Administer antibiotics to control secondary infection, and vaccinate the flock. Mass vaccination by spray or drinking water methods is not recommended. Individual bird administration by the eye-drop route is suggested. Follow the manufacturer’s instructions. In small poultry flocks, a swab may be used to remove tracheal plugs from gasping birds, followed by eye-drop vaccination.

**Prevention:** It is advisable to vaccinate birds using attenuated vaccine in endemic areas. Vaccination for LT is not as successful as for other diseases, but is an excellent preventive measure for use in outbreaks and in epidemic areas. Birds are vaccinated after 10 weeks of age by eye drop or aerosol spray. Birds that have recovered from ILT, or have been vaccinated against it, should not be added to flocks of susceptible birds because of their potential carrier status.

**Recovery:** Dispose of dead birds properly by deep burial, composting, or incineration. Depopulation, thorough disinfection of the premises and equipment, and resting of pens for 120 days are all necessary before restocking in order for a complete recovery to occur.

---

**Infectious Tenosynovitis**

**Other names:** viral arthritis, tenosynovitis, teno, reovirus enteritis, reovirus septicemia, malabsorption syndrome, helicopter disease.

**Clinical signs and lesions:** The principal sign of tenosynovitis is lameness with swelling of the tendon sheaths of the shank and the area extending above the hock. Affected birds are lame, sit on their hocks, and
are reluctant to move. Rupture of the tendon can occur in older roaster birds, resulting in permanent lameness of the affected leg.

Infection can also play a part in broiler stunting, the result of malabsorption syndrome. In chicks, malabsorption due to viral enteritis is called "helicopter disease" because feathering is affected, resulting in wing feathers protruding at various angles.

In commercial layer flocks, increased mortality may be the first sign of the septicemic form. Egg production will decrease by about two to three times the mortality rate. For example, a mortality rate of 5% will be accompanied by a 10-15% drop in egg production. In the septicemic form, joint involvement is present but less pronounced. Affected birds become cyanotic and dehydrated. The tips of the comb turns purplish. The entire comb darkens as the disease progresses.

**Differential diagnosis:** *Staphylococcus* infection, articular gout, and *Mycoplasma synoviae* infection should be considered.

**Cause, transmission, and epidemiology:** Several serotypes of the reovirus have been identified. Some localize in the joints (tenosynovitis) while others target respiratory or intestinal tissues (septicemic form). The virus is shed in the feces, and infection is by the respiratory and digestive tract routes. The infection spreads rapidly through flocks on the ground, but less rapidly in caged birds.

**Diagnosis:** A presumptive diagnosis can be made based on the appearance of the joints at necropsy. The direct demonstration of reovirus in the tendons or the isolation and identification of the virus can be used to make a definitive diagnosis.

**Treatment:** There is no satisfactory treatment available. In hens, supportive treatments like molasses, oyster shell therapy, and tetracycline to treat secondary bacterial infections may be helpful.

**Prevention:** A vaccine is available for use in endemic areas or on endemic farms.

**Recovery:** Once infection has occurred on a premises, it is not practical to eradicate it since the virus is relatively stable outside the bird. Vaccination will prevent disease and permit recovery of productivity.

---

**Lymphoid Leukosis**

**Other names:** visceral leukosis, leukosis, big liver, LL.

**Clinical signs and lesions:** Signs of lymphoid leukosis begin to show in birds only after the age of 16 weeks, because it has a long incubation period. Clinical signs are non-specific. The abdomen is distended as a result of an enlarged liver, the comb is reduced in size, and birds become emaciated and progressively weaker. If many birds in the flock are infected, egg production is reduced. Greenish diarrhea develops in terminal stages.

Lesions are usually restricted to internal organs. The liver, spleen, kidney, and ovary contain white or grey nodules consisting of cancerous lymphoid tissue that has spread from the bird's bursa.
**Differential diagnosis:** Lymphoid leukosis may be confused with Marek's disease, but the latter occurs in younger birds (from 3 weeks of age), and LL always involves the bursa of Fabricius.

**Cause, transmission, and epidemiology:** The cause of LL is a family of retroviruses, the avian leukosis viruses. Although primarily a disease of chickens, lymphoid leukosis can infect turkeys, guinea fowl, pheasants, and doves, but not on a large scale. Virus transmission occurs vertically through the egg to chick; the rate of transmission is low, but the chick is a life-long carrier and lays fewer eggs as a hen. Some horizontal transmission and infection through contact with contaminated environments also takes place.

**Diagnosis:** Tentative diagnosis is easily achieved by consideration of the age of affected birds, the lesions, and involvement of the bursa. For confirmation, the bursal tumors must be examined histologically. LL will result in tumors of the bursal follicles, while a rare MD-caused tumor of the bursa will be interfollicular.

**Treatment:** There is no treatment for LL.

**Prevention:** Obtaining chicks from LL-free breeders is the best prevention. The virus is present in the yolk and egg white of eggs from infected hens. Many national and international layer breeders have eradicated lymphoid leukosis from their flocks. The disease is still common in broiler breeder flocks.

**Recovery:** Because LL is primarily transmitted from breeders to progeny, recovery requires that replacement chicks are obtained from LL-free suppliers.

---

**Marek's Disease**

**Other names:** acute leukosis, neural leukosis, range paralysis, gray eye (when the eyes are affected), transient paralysis.

**Clinical signs and lesions:** Marek's disease is a type of avian cancer caused by a herpesvirus, which usually infects young birds. Chickens between 12 to 25 weeks of age are most commonly clinically affected. Occasionally pheasants, quail, game fowl, and turkeys can be affected. Clinical disease follows an incubation period of 3 weeks or more. Tumors in nerves cause lameness and paralysis. Tumors can occur in the iris, resulting in irregularly shaped pupils and blindness. Tumors of the liver, kidney, spleen, gonads, pancreas, proventriculus, lungs, muscles, and skin can cause incoordination, unthriftiness, paleness, weak labored breathing, and enlarged feather follicles. In terminal stages, the birds are emaciated, with pale, scaly combs, and greenish diarrhea. Mortality rates can be in excess of 60% in unvaccinated populations.

**Differential diagnosis:** Marek's disease is very similar to lymphoid leukosis, but Marek's usually occurs in chickens 12 to 25 weeks of age, while lymphoid leukosis usually starts at 16 weeks of age.

**Cause, transmission, and epidemiology:** Marek's disease virus is transmitted by air within the poultry house. It is in the feather dander, chicken house dust, feces, and saliva. Infected birds carry the virus in their blood for life, and are a source of infection for susceptible birds. Vertical transmission does not occur with MDV.
**Diagnosis:** The classical appearance of swollen peripheral nerves at necropsy and the distribution of lymphocytes in nerves will confirm a diagnosis of Marek's disease. In cases where the nerves are not affected, the age distribution of affected birds will help to differentiate MD from LL.

**Treatment:** None.

**Prevention:** Chicks can be vaccinated at the hatchery. While the vaccination prevents tumor formation, it does not prevent infection by the virus.

**Recovery:** Marek's disease is very stable in feather dander, and infectious virus can remain on infected premises for very long periods of time. Once infection has occurred, future infections will occur and the disease can only be prevented with vaccination. Birds with clinical signs of disease will not recover and should be culled.

---

**Mycoplasma gallisepticum Infection**

**Other names:** CRD, *Mycoplasma gallisepticum*, MG, infectious sinusitis, mycoplasmosis.

**Clinical signs and lesions:** Chickens, turkeys, pigeons, ducks, peafowl, and passerine birds can be infected. Clinical symptoms vary slightly between species. Infected adult chickens may show no outward signs if infection is uncomplicated. However, sticky, serous exudate from nostrils, foamy exudate in eyes, and swollen sinuses can occur, especially in broilers. The air sacs may become infected. Infected birds can develop respiratory rales and sneezing. Affected birds are often stunted and unthrifty.

The clinical signs in turkeys are more pronounced than in chickens. There are two forms of this disease in turkeys. In the "upper form" the birds have watery eyes and nostrils, the infraorbitals (just below the eye) become swollen, and the exudate becomes caseous and firm. The birds have respiratory rales and show unthriftiness. In the "lower form" infected turkeys develop airsacculitis. As with chickens, birds may show no outward signs if the infection is uncomplicated. These birds may be condemned at slaughter or may act to carry the bacteria to naïve birds. The appearance of MG in other species will be similar to infections in turkeys.

CRD in embryos can cause dwarfing, airsacculitis, and death.

**Differential diagnosis:** Clinically, the disease may be indistinguishable from infectious synovitis, which is caused by *Mycoplasma synoviae*. The swollen sinuses caused by MG may also look like fowl cholera or swollen head syndrome (metapneomovirus).

**Cause, transmission, and epidemiology:** *Mycoplasma gallisepticum* can be transmitted to offspring through the egg. Commercial breeding flocks, however, should be MG-free. Introduction of infected replacement birds can introduce the disease to MG-negative flocks. MG can also be spread by using MG-contaminated equipment.

**Diagnosis:** Clinical disease and typical lesions can lead to a presumptive diagnosis of MG, but a definitive diagnosis is only possible through the isolation of the causative organism and its identification with specific antisera. Alternatively, the testing of paired sera (pre- and post-exposure) can also support a diagnosis.
Treatment: Outbreaks of MG can be controlled with the use of antibiotics. Erythromycin, tylosin, spectinomycin, and lincomycin all exhibit anti-mycoplasma activity, and have given good results. Administration of most of these antibiotics can be by feed, water, or injection. These are effective in reducing clinical disease. However, birds remain carriers for life.

Prevention: Eradication is the best control for mycoplasma disease. This can be done by testing breeders, isolating infected flocks, and heat or antibiotic treatment of their eggs.

Recovery: Generally, once a farm has had a flock infected with mycoplasma, subsequent flocks will become infected. Premises can eliminate MG by hatching MG-free eggs (heating or antibiotic treatment method or from breeders free of MG) and placing them in a clean environment with very strict biosecurity in place. If biosecurity cannot be achieved then recovery is probably not possible and vaccination may be a better option.

**Mycoplasma meleagridis Infection**

Other names: MM, N strain, H strain.

Clinical signs and lesions: A decrease in egg production and hatchability is seen in turkey breeders. There can be very high mortality in young poults. Unthriftiness, respiratory distress, stunting, crooked neck with deformity of cervical vertebrae, and leg deformation are common in young birds.

Differential diagnosis: Although typical of mycoplasmosis, the gross lesions of MM (especially in the air sac) cannot be differentiated from those caused by other *Mycoplasma* spp.

Cause, transmission, and epidemiology: This bacterial disease affects turkeys of all ages, although poults are affected more severely than mature turkeys. MM has been shown to infect pigeons, quail, and peafowl.

Egg transmission is low in the early breeding period, but rises as the age of the flock increases. Infections can be introduced into a flock by contaminated equipment, shoes, and clothing of workers and visitors. Hens can become infected by insemination with MM-containing semen.

Diagnosis: Clinical disease and typical lesions can lead to a presumptive diagnosis of MM, but a definitive diagnosis is only possible through the isolation of the causative organism and its identification with specific antisera. Alternatively, the testing of paired sera (pre- and post-exposure) can also support a diagnosis.

Treatment: Several antibiotics have been effective in treatment, including tylosin, erythromycin, spectinomycin, and lincomycin-spectinomycin.

Prevention: The best preventive measure is to keep MM-free breeders. The MM-free status of breeders can be confirmed by periodic blood tests and managed as outlined for MG.

Recovery: Generally, once a farm has had a flock with mycoplasma, subsequent flocks will be infected. Premises can eliminate MM by hatching MM-free eggs and placing them in a clean environment with very strict biosecurity in place. If biosecurity cannot be achieved, then recovery is probably not possible.
Mycoplasma synoviae Infection

Other names: MS, infectious synovitis, tenovaginitis

Clinical signs and lesions: This disease occurs in chickens and turkeys. Early signs are respiratory difficulty, lameness, and a tendency of birds to rest on the floor. It occurs in growing birds. Other signs are pale combs, swollen hock joints, greenish diarrhea, an unwillingness to move to feed and watering troughs, loss of weight, and breast blisters (a result of persistent floor rest, as well as synovitis of the keel joint sac). In layer flocks there is a transient drop in egg production.

Although infectious synovitis is predominantly a disease of the upper respiratory tract, the infection spreads throughout the body, resulting in inflammation of the joints of many infected birds. In the respiratory tract, mild inflammation may be seen in the trachea and air sacs. The consistency of synovial fluid from infected joints will be affected. Putting a drop of synovial fluid between the thumb and forefinger and then spreading apart will result in a long string, if normal. In an infected joint, a string will not form from the fluid.

Differential diagnosis: Clinically, the disease is indistinguishable from chronic respiratory disease, caused by Mycoplasma gallisepticum. Diseases that may show similar signs and lesions are staphylococcal arthritis and infectious tenosynovitis (viral arthritis).

Cause, transmission, and epidemiology: Infectious synovitis is caused by Mycoplasma synoviae (MS). Egg (vertical) transmission is the more important mode of transmission of MS, but it is also transmitted by contact and air droplets (respiratory route) between birds.

Diagnosis: Clinical signs and lesions provide information for a dependable tentative diagnosis. It can be confirmed by isolation of the causative organism on an MS media or in embryonating chicken eggs.

Treatment: Lame birds can not be successfully treated, but several antibiotics have been used to reduce losses, especially when given by injection rather than in feed or water. Birds recover slowly for both respiratory and synovitis forms. Several antibiotics are variably effective. The most effective are tylosin, erythromycin, spectinomycin, lincomycin, and chlorotetracycline.

Prevention: Use replacement chicks from certified MS-free breeders. The all-in, all-out management system helps to avoid a build-up of Mycoplasma on a poultry farm. Eradication is the best and only sure control. Manage breeders as outlined for MG to create MS-free flocks.

Recovery: Generally, once a premises has had a flock with mycoplasma, subsequent flocks will be infected. Premises can eliminate MS by hatching MS-free eggs and placing them in a clean environment with very strict biosecurity (especially isolation) in place. If biosecurity cannot be achieved, then recovery to an MS-free status is probably not possible.
Mycotoxins (fungal toxins)

GENERAL INFORMATION

Mycotoxins are toxic substances produced by fungi. They are toxic for birds and mammals although the amount that is toxic may vary by species. As a general rule, grain or feed that is toxic for birds or other animals should never be given to humans.

Diagnosis: A presumptive diagnosis can be made based on feed examination and recovery of the flock when replaced with good feed. A definitive diagnosis of mycotoxins involves isolation, identification, and quantification of the specific toxin(s).

Treatment: Remove the toxic feed and replace it with good feed. Treat concurrent diseases (parasitic, bacterial) identified during diagnosis. Vitamins, trace minerals (selenium), and protein requirements are increased by some mycotoxins, and can be compensated for by feed formulation and water-based treatment.

Prevention: Prevention is based on detection of contaminated ingredients and their exclusion from rations, if possible. The correct storage of ingredients is necessary. Mold inhibitors such as propionate and gentian violet added to feed will suppress proliferation of fungi and elaboration of toxins. Mycotoxins can form in decayed, crusted, built-up feed in feeders, feed mills, and storage bins.

Recovery: Cases will re-occur if mycotoxins are formed on the farm because feed is not handled properly. If, however, the cause of the contamination is corrected and/or the source removed, there is no residual risk.

Mycotoxins: Aflatoxicosis

Other names: Turkey X disease.

Clinical signs and lesions: This is primarily a disease of the liver, but affects other body functions, causing reproduction problems and death in affected birds. Turkey poults and ducklings are highly susceptible. The affected birds show depression, inappetence, reduced growth rate, loss of condition, bruising, a decrease in egg production, fertility and hatchability, and increased mortality. Some birds may develop ataxia, convulsions, and opisthotonos. Aflatoxicosis is associated with increased susceptibility to infectious disease, due to its immunosuppressive effects.

Differential diagnosis: Other mycotoxicoses, infectious bursal disease, lymphoid leukosis.

Cause, transmission, and epidemiology: Aflatoxin is produced by Aspergillus flavus, A. parasiticus, and/or Penicillium puberulum growing on the feed. The mycotoxins of the aflatoxin group are identified as B1; B2, G1, and G2. Aflatoxin B1 is the most common in grains and is highly toxic. The production of the toxin occurs when the substrate, temperature, and humidity are ideal for fungal growth. Grains damaged by insects and drought stress, and broken pieces of grain are more likely to support fungal growth and toxin formation. Aflatoxin B1 is a potent, naturally-occurring carcinogen, and hence a public health consideration.
Diagnosis: On postmortem examination of birds with aflatoxicosis, there is jaundice, generalized edema, hemorrhages, swollen kidneys, and the liver is tan or yellow. There may be marked catarrhal inflammation of the duodenum and excessive bile production. Some degree of increased peritoneal fluid (ascites) and visceral edema is usually evident.

Mycotoxins: Citrinin Mycotoxicosis

Clinical signs and lesions: Citrinin mycotoxicosis affects chickens, turkeys, and ducklings. Affected birds have watery droppings due to increased water intake and output, as well as metabolic alterations of electrolytes and acid-base balance. Young birds have reduced weight gain.

Usually, only mild lesions are present on the kidneys, which may be swollen. Lymphoid depletion and liver necrosis may also be present.

Differential diagnosis: Other mycotoxicoses, parasitism, excess dietary salt.

Cause, transmission, and epidemiology: This toxin is produced by *Penicillium citrinum*, other species of *Penicillium*, and some *Aspergillus* species.

Mycotoxins: Ergotism

Clinical signs and lesions: In poultry, ergotism causes neurologic, vascular, and endocrine symptoms, including reduced feed intake and growth; necrotic beak, comb, and toes; vesicular dermatitis; diarrhea; incoordination; and decreased egg production.

Differential diagnosis: Other mycotoxicoses.

Cause, transmission, and epidemiology: The common causes are parasitic plant fungi, *Claviceps purpurea* and other *Claviceps* species, that colonize wheat and rye to produce ergot alkaloids, compounds causing ergotism in man and animals. The alkaloid causes constriction of the blood vessels. It is transmitted through contaminated feed.

Mycotoxins: Ochratoxicosis

Clinical signs and lesions: Ochratoxins are among the most toxic mycotoxins (fungal toxins) to poultry. The toxins are nephrotoxic. Clinical signs include feed refusal and increased mortality. Weight loss and reduced egg production can also occur.

Acute lethal Ochratoxin A toxicity causes pale liver, pancreas and kidneys; swollen kidneys; enteritis; airsacculitis; white urate deposits in the ureters; and visceral urate deposition. There is tubular nephrosis. Subacute Ochratoxin A causes increased kidney and liver weight, and decreased weight of lymphoid organs. There is reduction in plasma carotenoids, immune function, and certain blood coagulation factors.

Differential diagnosis: Other mycotoxicoses, severe dehydration.
Poultry Disease Handbook for Africa

**Cause, transmission, and epidemiology:** Ochratoxins A, B, C, and D, and their methyl ethyl esters are produced by *Penicillium viridicatum* and *Aspergillus ochraceous*, which grow on numerous grains and feedstuffs.

**Ochratoxins: Oosporein Mycotoxicosis**

**Clinical signs and lesions:** Oosporein is a red, toxic, dibenzoquinone. Oosporein mycotoxicosis causes a dose-related decrease in growth and an increase in water consumption. Chickens are more susceptible than turkeys.

It causes visceral and articular gout, swollen pale kidneys due to nephrotoxicity, and mortality. The liver is mottled with focal necrosis and gall bladder is distended.

**Differential diagnosis:** Other mycotoxicoses, severe dehydration.

**Cause, transmission, and epidemiology:** The toxin is produced by *Chaetomium* species and other fungi that are contaminants of cereal grains and feedstuffs.

**Mycotoxins: Trichotheccene Mycotoxicosis**

**Other names:** Fusariotoxicosis

**Clinical signs and lesions:** These mycotoxins cause caustic injury to the skin and mucous membranes. They cause reduced growth, rickets, digestive and nervous signs, cyanotic combs and wattles, abnormal feathering, severe depression, and decreased egg production. Pigeons, ducks, turkeys, and geese are also affected to varying degrees. Feed refusal is a common clinical sign, as well as increased water consumption.

Hens with oral lesions may have associated yellow-tan, friable livers at necropsy, as well as swollen kidneys, urate deposits in ureters, ulceration and inflammation of the crop mucosa, and a thickened, roughened gizzard lining. Other reported lesions are mottling of the liver, distension of the gall bladder, atrophy of the spleen, and visceral hemorrhages.

**Differential diagnosis:** Other mycotoxicoses, excess dietary protein, severe dehydration.

**Cause, transmission, and epidemiology:** Trichothecenes are produced by soil and plant fungi, including *Fusarium* spp., which produces about 20% of the more than 100 trichothecenes known to exist. The compounds occur in contaminated feed and litter. T-2 toxin is the most toxic to poultry.

**Mycotoxins: Zearalenone Mycotoxicosis**

**Clinical signs and lesions:** This fungal toxin causes reproductive failure in swine, but poultry are more resistant. In broiler breeders, it causes a reduction in egg production and egg quality without a decrease in hatchability or fertility. Turkeys are more sensitive, and the active compound, zearalenone, causes estrogen-like effects on the reproductive tract and hormone-sensitive tissues. Experimentally inoculated male poults
develop dewlaps and soft tissue swelling in the vent area, as well as precocious strutting behavior. In experimentally inoculated geese, fertility and spermatogenesis are reduced.

Lesions in affected birds include ascites, and cysts inside and outside the oviduct. Oviducts are swollen and inflamed, and are obstructed with fibrinous fluid. Oviducts may rupture.

**Cause, transmission, and epidemiology:** Zearalenone is a mycotoxin produced by *Gibberella zeae* (*Fusarium roseum, F. graminearum*). Warm humid conditions followed by cooler temperatures encourage growth and toxin production.

---

**Necrotic Enteritis**

**Other names:** enterotoxemia, rot gut.

**Clinical signs and lesions:** Initially, birds show a reduction in feed consumption, as well as dark, often blood-stained feces. Infected chickens will have diarrhea. Chronically affected birds become emaciated. The bird, intestines, and feces emit a fetid odor.

**Differential diagnosis:** Necrotic enteritis should be differentiated from ulcerative enteritis and coccidiosis. This can be complicated when necrotic enteritis and coccidiosis appear concurrently, as is often the case.

**Cause, transmission, and epidemiology:** The disease is caused by the bacterium *Clostridium perfringens*. Rapidly growing young birds, especially chickens and turkeys 2-12 weeks of age, are most susceptible. Necrotic enteritis is a disease associated with domestication and is unlikely to threaten wild bird populations. It is primarily a disease of broilers, roasters and turkeys. Ulcerative enteritis, on the other hand, commonly affects pullets and quail.

Necrotic enteritis does not spread directly from bird to bird. Bacteria are ingested along with infected soil, feces, or other infected materials, then grow in the intestinal tract. Infection commonly occurs in crowded or immunosuppressed flocks, and flocks maintained in poor sanitary conditions.

**Diagnosis:** The diagnosis of necrotic enteritis (NE) can be made on the basis of typical gross and histologic lesions in the intestine. An absence of liver lesions will help to rule out ulcerative enteritis. The causative agent can be isolated to confirm the specific diagnosis.

**Treatment:** The clostridium bacteria involved in necrotic enteritis is sensitive to the antibiotics bacitracin, neomycin, and tetracycline. However, antibiotics such as penicillin, streptomycin, and novobiocin are also effective. Bacitracin is the most commonly used drug for control of necrotic enteritis.

**Prevention:** Prevention includes the control of coccidia, the use of preventative levels of medication, and good sanitation, husbandry, and management.

**Recovery:** *Clostridium perfringens* is a spore-forming organism, and infectious spores will remain in the soil after an outbreak. Over time, the spores will be dispersed, resulting in lowered exposure for naïve birds, but risk will not disappear. Controlling predisposing factors like immunosuppressive diseases and internal parasites will make birds more resistant. In highly susceptible species like quail, preventative medication may be the only means of having sustainable production.
Newcastle Disease

Other names: Sometimes called pneumoencephalitis, exotic Newcastle disease, Asian Newcastle disease or pigeon paramyxovirus. Newcastle disease is referred to by its three virulence types — mildly pathogenic (lentigenic), moderately pathogenic (mesogenic), and very pathogenic (velogenic). It may also be classified according to the tissue tropism of the virus: pneumotropic (respiratory system), viscerotropic (gastrointestinal tract and other internal organs), or neurotropic (nervous system).

Clinical signs and lesions: Newcastle disease is characterized by the sudden onset of clinical signs, which include hoarse chirps, watery discharge from nostrils, labored breathing (gasping), facial swelling, paralysis, trembling, and twisting of the neck. Mortality ranges from 10 to 80%, depending on host immunity and the pathogenicity of the responsible strain.

The mildly pathogenic strains may cause reduced egg-laying and mild respiratory signs. Moderately pathogenic strains may cause transient nervous signs, a drastic reduction in egg-laying, and the production of soft-shelled eggs, in addition to mild respiratory signs. Lesions outside the respiratory system include hemorrhages in the ovaries and proventriculus, and sometimes plaques and hemorrhages in the gizzard, intestinal lining, and caecal tonsils. The very virulent strains of ND cause signs similar to those caused by the moderately pathogenic strains, but mortality rates are high and can wipe out the entire flock. Newcastle disease can cause a mild conjunctivitis in humans and other mammals.

In hosts that have some immunity, infections and clinical disease may still occur. However, signs will be milder. For example, a velogenic ND infection in an immune bird may resemble a mesogenic or lentigenic ND infection.

Differential diagnosis: Avian influenza, infectious bronchitis, infectious laryngotracheitis.

Cause, transmission, and epidemiology: Newcastle disease virus (NDV) belongs to the Paramyxovirus Type 1 group. It is believed that local, free-roaming chickens serve as reservoirs of infection for newly-hatched local birds and commercial birds. However, serious seasonal outbreaks (December – March) of velogenic ND occur annually in village chickens in West Africa. Guinea fowl may harbor the virus but show no or mild clinical signs. They may be the source of outbreaks in village chickens in certain parts of West Africa.

In live birds, the virus is shed in body fluids, secretions, excreta, and droplets from the breath of infected birds. During an outbreak, the virus is spread in exhaled air, respiratory discharges, feces and on eggs. Eggs from velogenic strain-infected flocks may also have NDV internally. Healthy birds may be infected from these sources, and hatcheries from infected eggs.

NDV can also be transmitted by contaminated shoes, caretakers, feed deliverers, visitors, tires, dirty equipment, feed sacks, crates, and wild birds. The virus can be passed in the egg, but Newcastle-infected embryos usually die before hatching. Embryos may survive if the dam has ND immunity.

Diagnosis: The signs and lesions of ND cannot be differentiated from other causes without laboratory testing. Definitive diagnosis may be made by isolation of the virus in Newcastle antibody-free chicken embryonated eggs, and identification of the virus by the hemagglutination-inhibition test. Serology showing rising antibody titers may demonstrate exposure.
Treatment: There is no specific treatment; antibiotics administered for 3-5 days to help prevent secondary bacterial infections (especially E. coli) in mild cases are useful. For chicks, increasing the brooding temperature by 5°F may help reduce losses.

Prevention: Good sanitation and implementation of a comprehensive biosecurity program are necessary to prevent Newcastle disease. Well-designed vaccination schedules, using low-virulence live vaccines, give very effective immunization results. Inactivated oil-emulsion vaccines administered to the parent flock before onset of egg dropping ensure passive immunity in day-old chicks. Active immunization is induced in the chicks just when their passively-acquired antibody levels are dropping. A second vaccination four weeks later gives life-long protection if proper vaccination procedures are applied.

Recovery: Depopulation and thorough disinfection of the premises are recommended.

Omphalitis

Other names: Navel-ill, yolk-sac disease, mushy chick disease.

Clinical signs and lesions: Affected chicks show dullness and a lack of appetite. Morbidity and mortality rates are variable. Diarrhea, with a pasty vent area, is characteristic. The vent area and cloaca are sometimes plugged by dried feces and unabsorbed yolk sac, containing abnormal yolk material (thin or thick, cheesy, greenish, or containing blood). External infection of the navel may be present. Edema of the skin of the ventral body area, septicemia, and dehydration may occur. There are often fibrin deposits on the surfaces of abdominal organs.

Differential diagnosis: Pullorum disease and other Salmonella infections in chicks.

Cause, transmission, and epidemiology: Several bacterial species can singly or in combination cause this disease. However, the most common cause is Escherichia coli, in which case the disease is also called colibacillosis. Other causative organisms can be various species of Staphylococcus.

The causative bacteria are widely distributed in nature and may contaminate water and the soil. E. coli in particular is a normal resident of the intestine, and may contaminate feed and water through fecal contamination. It may infect ovaries and thereby infect chicken embryos before they are hatched. However, contamination of hatching eggs is the most common mode of transmission of omphalitis in chicks. Infection occurs at the time of hatching or shortly thereafter, before the navel is healed. Chicks from dirty hatching eggs, eggs with poor quality shells, or newly hatched chicks placed in dirty holding boxes are most susceptible. Chicks removed prior to complete healing of the navel due to improper temperature and/or humidity are also more susceptible. Eggs that explode in the hatching tray contaminate other eggs in the tray and increase the incidence.

Diagnosis: Clinical signs and postmortem lesions are strongly suggestive. Diagnosis is confirmed by isolation in profuse culture of the bacterial agent and identification.

Treatment: Most affected birds die in the first few days of life. Prompt treatment with a suitable antibacterial agent may be successful for a flock, although individual birds may not recover.
**Poultry Disease Handbook for Africa**

**Prevention:** Control is by prevention through effective hatchery sanitation, hatchery procedures, breeder flock surveillance, and proper pre-incubation handling of eggs. Mushy chicks should be culled from the hatch and destroyed. If chick mortality exceeds 3%, the breeder flocks and egg handling and hatching procedures should be reviewed. In village chickens, eggs should be cleaned with a clean, dry cloth before they are given to hens for brooding. Nest areas should be kept clean and dry.

**Recovery:** Stunted chicks should be removed and destroyed; surviving chicks should be moved into a cleaner pen, and the contaminated one cleaned and disinfected. If the conditions leading to the problem are resolved, there is no residual risk.

**Predators**

Predation from mongoose, kites, hawks, wild and domestic dogs, and cats can be a large problem for poultry keepers.

Predation is best controlled by housing/sheltering poultry at night, keeping a close watch on the birds while they are scavenging, killing stray dogs/cats/mongoose, chasing away and trapping predators (kites and hawks), and repairing housing, shelters, and coops regularly. The proper disposal of poultry carcasses and offal will prevent the attraction of predators.

**Riemerella anatipestifer Infection**

**Other names:** New duck disease, duck septicemia, infectious serositis

**Clinical signs and lesions:** *Riemerella anatipestifer* (formerly *Pasteurella anatipestifer*) is primarily a disease of ducks causing a fowl cholera-like disease syndrome. Infected ducks may show ocular and nasal discharge, coughing and sneezing, have greenish diarrhea, and exhibit ataxia, head and neck tremors, listlessness, and coma. Mortality in affected flocks may reach 5-75%.

Turkeys can also be infected with *Riemerella anatipestifer* and as a sequelae may develop abscessation of the moveable vertebrae in the back (T4) resulting in paralysis of the legs.

In ducks, fibrinous exudate is seen most commonly in the pericardial cavity, in air sacs, and on the surface of the liver. Chronic infections under the skin and sometimes in the joints may develop.

**Differential diagnosis:** Fowl cholera caused by *Pasteurella multocida* should be differentiated.

**Cause, transmission, and epidemiology:** The disease is caused by the bacterium *Riemerella anatipestifer*. It is transmitted through the respiratory tract or through open wounds, especially those on the feet, especially between ducks. There is some evidence, based on seasonal occurrence, that the disease may also be transmitted to turkeys by arthropod vectors.

**Diagnosis:** *Riemerella anatipestifer* cannot be differentiated from *P. multocida* without the culture and identification of the disease agent. However, based on clinical signs and case history, riemerellosis or fowl cholera can be presumed. Because treatment of these two conditions is similar, a presumptive diagnosis may be sufficient to begin managing the condition although a definitive diagnosis will help in eliminating risk factors.
Treatment: Antibiotics, primarily sulfamethazine, sulfaquinoxaline, novobiocin, penicillin, enrofloxacin, and lincomycin have proven effective, in the field and experimentally, at preventing the onset of disease or reducing morbidity and mortality. Tetracyclines are ineffective.

Prevention: Riemerella anatipestifer is usually introduced to domestic birds from other domestic birds or free-flying ducks. If the source of the disease agent is identified and the birds are isolated from that source, then new cases can be prevented with biosecurity.

Recovery: After treatment, there is no residual risk if sources are identified and new infections are prevented. Turkeys that have been infected and have recovered may develop vertebral abscesses from which they will not recover. Paralyzed turkeys should be culled as soon as they are observed.

Salmonellosis: Fowl Typhoid

Fowl typhoid causes high mortality in young birds and is usually an asymptomatic infection in adults. Hens that are chronic carriers transmit the disease to their embryos through the egg. The Fowl typhoid has been eradicated from commercially raised poultry in the United States and many other developed countries, but may persist in backyard flocks.

Other names: Gallinarum

Clinical signs and lesions: In newly hatched chicks, poults or keats, the clinical signs of fowl typhoid can include depression, loss of appetite, somnolence, droopy wings, huddling, dehydration, thirst, ruffled feathers, and weakness. Yellow or green diarrhea with pasting of the vent feathers is common, and birds may be blind or have swollen joints. Birds that survive are usually small and underweight, unthrifty and may never become sexually mature.

In growing and adult birds, the disease can be silent. When the infection is symptomatic, clinical signs may include inappetance, depression, ruffled feathers, pale and shrunken combs, diarrhea, or a droopy appearance. There may also be a decrease in egg production or fertility. In turkeys, a characteristic sign is the appearance of small, white plaques visible through the wall of the intestine. In guinea fowl, the lesions often involve the respiratory tract.

In adult birds, the lesions at necropsy may be minimal. In some animals, there may be a mottled pancreas, excess pericardial fluid, fibrinous pericarditis, or caseous granulomas in the lungs and air sacs. The testes sometimes contain white foci or nodules. Chronic carrier hens may have nodular or regressing ovarian follicles, or a few misshapen ova among normal ovules. In hens, caseous material is often found in the oviduct, and peritonitis, perihepatitis, or ascites may be seen.

Differential diagnosis: Other conditions in young birds that may present similar clinical signs are omphalitis, diseases caused by other Salmonella species, especially S. pullorum, and chilling. In adults, colibacilosis, paratyphoid, chlamydiosis or other bacterial septicemias can look similarly. The granulomatous lesions of fowl typhoid are similar in appearance to those of Hjarre’s disease (E. coli), tuberculosis, aspergillosis, histomoniasis, Marek’s disease, or reticuloendotheliosis (a retroviral disease that causes tumors).

Cause, transmission, and epidemiology: The causal agent is the bacterium Salmonella enterica subsp. enterica serovar Pullorum-Gallinarum (previously called S. gallinarum) which is pathogenic only to poultry.
Although respiratory and fecal-oral spread is possible, the organism is most significantly spread through the infected eggs of carrier hens to progeny. From this vertical mode of infection, hatched chicks can then transmit the infection horizontally to other chicks through infected secretions or feces. It can spread further through contaminated incubators, hatchers, chick boxes, houses, equipment, poultry by-product feedstuffs, and carrier birds.

**Diagnosis:** Tentative diagnosis may be made based on history, clinical signs and postmortem lesions. Definitive diagnosis is based on agglutination tests, isolation of a Group D *Salmonella*, and identification of the causative agent, *Salmonella enterica* subsp. *enterica* serovar Pullorum-Gallinarum.

**Treatment:** Results of treatment of are poor. Treatment is for flock salvage (slaughter) only. Several sulfonamides, antibiotics, and antibacterials are effective in reducing mortality, but none eradicates the disease from the flock. Survivors remain stunted and act as carriers. Eradication requires destroying the entire flock.

**Prevention:** In commercial poultry production prevention should be aimed at maintaining breeders that are free from infection. These flocks should be tested serologically using the rapid plate agglutination test, and then confirmed with the tube agglutination test. Both tests employ stained *S. gallinarum* antigen, which is commercially available.

Incubator and hatching units should be properly disinfected, and if possible, the hatching operation should be in a quarantined, Salmonella-free area. Poultry farmers should ensure that they obtain chicks from pullorum/gallinarum-free breeders and hatcheries.

**Recovery:** The entire flock must be culled, and the poultry house properly disinfected and left empty for about a month before re-stocking to break the infection cycle.

**Salmonellosis: Paratyphoid**

**Other names:** Salmonellosis

**Clinical signs and lesions:** This is a systemic condition and clinical signs may include diarrhea, inappetence, unthriftiness, and respiratory signs. Lesions observed in birds that have died of salmonellosis (paratyphoid) are similar to those seen in pullorum disease. The livers are enlarged and bile-stained, and may have pale, necrotic patches. The spleen and kidneys are also enlarged, and the blood is thin and watery. The intestinal lining may have raised plaques, and the caecal content cheesy, both as the result of intestinal epithelial necrosis.

**Differential diagnosis:** Fowl cholera, pullorum disease, chronic respiratory disease, colibacilosis

**Cause, transmission, and epidemiology:** Paratyphoid may be caused by over 200 species of *Salmonella*. The most common of these are *S. typhimurium*, *S. enteritidis*, and *S. heidelberg*.

Egg-transmission occurs in paratyphoid, but transmission through contaminated water and feed is equally important. Infected birds remain carriers for a long time, possibly for life. The bacteria localize in the gall bladder and are regularly excreted in the feces to serve as source of contamination. Rodents, lizards, and humans are also known reservoirs for paratyphoid organisms.
Most of the *Salmonella* spp. that can cause paratyphoid in poultry can also cause diarrhea in humans. *S. enteritidis* in particular, can be transmitted from an infected hen to its egg. Contaminated eggs have caused outbreaks of salmonellosis in humans. Proper handling of eggs and meat, hygiene when handling food, and cooking before consumption can prevent human disease.

**Diagnosis:** The isolation or detection of non-pullorum, non-gallinarum *Salmonella* sp. from viscera is diagnostic. The detection of *Salmonella* sp. from intestines can be a normal finding.

**Treatment:** Antibiotics can be used to treat paratyphoid infections but the wisdom of their use is debatable. *Salmonella* spp. are part of the normal flora of many poultry species, and using antibiotics to eliminate them is not likely to be effective over the long term.

**Prevention:** There are several commercial vaccines that can be used to prevent infections. They are not usually cost effective for use in small flocks but are a critical preventative measure in commercial flocks, where infections may result in human infections.

**Recovery:** Paratyphoid salmonella are normal in poultry environments. Treating any underlying disease conditions that have predisposed the birds to

### Salmonellosis: Pullorum

**Other names:** Bacillary White Diarrhea, BWD.

**Clinical signs and lesions:** Chicks are weak and may die, with morbidity and mortality rising 4-5 days after hatch. Signs include drowsiness, huddling, droopiness, and lack of appetite, but because of fever, birds tend to drink excessively. Respiratory distress may be seen, but characteristically diarrhea, showing as a white pasty vent area, is a major manifestation of pullorum disease. Sometimes the feces are stained with green bile. Survivors become asymptomatic carriers with localized infection in the ovary.

Postmortem examination of chicks shows the following changes:

- Pasty white feces in the cloacal area.
- Grey patches (nodules) in the lungs, gizzard wall, heart, and intestinal wall.
- Intestinal contents whitish and fluid or cheesy.
- Pin-point hemorrhage or grayish dead patches may be seen in the liver.
- Enlarged spleen.
- Ureters distended with whitish uric acid crystals.

**Differential diagnosis:** Other conditions that may present similar clinical signs are omphalitis, diseases caused by other *Salmonella* species, especially *S. gallinarum*, and chilling.

**Cause, transmission, and epidemiology:** The causal agent is the bacterium *Salmonella enterica* subsp. *enterica* serovar Pullorum-Gallinarum (previously called *S. pullorum*) which is pathogenic only to poultry. Although respiratory and fecal-oral spread is possible, the organism is most significantly spread through the infected eggs of carrier hens to progeny. From this vertical mode of infection, hatched chicks can then transmit the infection horizontally to other chicks through infected secretions or feces. It can spread
further through contaminated incubators, hatchers, chick boxes, houses, equipment, poultry by-product feedstuffs, and carrier birds.

**Diagnosis:** Tentative diagnosis may be made based on history, clinical signs and postmortem lesions. Definitive diagnosis is based on agglutination tests, isolation of a Group D *Salmonella*, and identification of the causative agent, *Salmonella enterica* subsp. *enterica* serovar Pullorum-Gallinarum.

**Treatment:** Results of treatment of pullorum disease are poor. Treatment is for flock salvage only. Several sulfonamides, antibiotics, and antibacterials are effective in reducing mortality, but none eradicates the disease from the flock. Survivors remain stunted and act as carriers. Eradication requires destroying the entire flock.

**Prevention:** In commercial poultry production prevention should be aimed at maintaining parent stock free from infection. These flocks should be tested serologically using the rapid plate agglutination test, and then confirmed with the tube agglutination test. Both tests employ stained *S. pullorum* antigen, which is commercially available.

Incubator and hatching units should be properly disinfected, and if possible, the hatching operation should be in a quarantined, pullorum-free area. Poultry farmers should ensure that they obtain chicks from pullorum-free hatcheries.

**Recovery:** The entire flock must be culled, and the poultry house properly disinfected and left empty for about a month before re-stocking to break the disease cycle.

---

**Staphylococcus Infection**

**Other names:** staph septicemia, staph arthritis, bumblefoot, staph.

**Clinical signs and lesions:** Staphylococcal infections appear in three forms -- septicemia (acute), arthritic (chronic), and bumblefoot. The septicemic form is similar to fowl cholera in that the birds are listless, without appetite, feverish, and show pain during movement. Black rot may show up in eggs (the organism is passed in the egg). Infected birds pass fetid, watery diarrhea. Many will have swollen joints, and decreased egg production. The arthritic form follows the acute form. Birds show symptoms of lameness and breast blisters, as well as painful movement. They are reluctant to walk, preferring to sit rather than stand. Bumblefoot is a localized chronic staph infection of the foot, thought to be caused by puncture injuries. Affected birds become lame from swollen foot pads. Bumblefoot is especially common in waterfowl (ducks and geese).

**Differential diagnosis:** Fowl cholera for septicemic form, infectious tenosynovitis, Marek’s disease for the arthritic form, and traumatic injury for bumblefoot.

**Cause, transmission, and epidemiology:** The causative agent, *Staphylococcus aureus*, is soil-borne, and outbreaks in flocks often occur after storms, especially when birds on range drink from stagnant rain pools or are otherwise exposed to unclean water. It may also stem from hatchery infections (see Omphalitis).

**Diagnosis:** A definitive diagnosis is based on the clinical appearance of the disease and the recovery of the causative bacteria.
Treatment: Novobiocin can be given in the feed for 5-7 days. Erythromycin and penicillin can be administered in the water for 3-5 days or in the feed for 5 days. Other antibiotics and drugs are only occasionally effective.

Recovery: If the immediate environment of the birds is cleaned or changed after treatment, there will be no residual risk of infection on the premises to new birds.

Stress

Physiological reaction to stress: Stress acts on the hypothalamus resulting in the release of corticotrophin releasing factor (CRF). CRF stimulates the anterior pituitary gland to release adrenocorticotrophin hormone (ACTH), which acts on the adrenal gland medulla to release epinephrine, norepinephrine, and adrenorphines. These compounds have an effect on energy metabolism (an increase in lipolysis, glycogenolysis, and insulin production, and a decrease in gluconeogenesis and glucose utilization), and blood flow (an increase in blood flow to skeletal muscles, heart muscles, brain, skin, and gastrointestinal tract, as a result of increased heart rate and contraction and increased blood volume). Energy that could have been used in the production of more meat and eggs is instead used to respond to stress.

Causes of stress: A husbandry system can be stressful if it exerts abnormal or extreme demands on the birds. Stresses can be mental, physical, or a combination of both.

Family poultry are subjected to mental stress (pain, fear, anxiety) during a variety of common activities including:

- Catching
- Being chased by predators
- Running away from vehicles
- Tying and wing restraint
- Bundling in crates ("tenga")
- Riding on vehicle roof tops for transportation
- Not having adequate food or water

The mental stress associated with these activities may be caused by visual, auditory, social, and/or physical factors.

Birds are subjected to physical stress (environmental, such as heat, cold, wind, strokes, wounds, etc.) through injuries and by actions such as:

- Being caught by the legs and tied in groups
- Holding upside down
- Loading and unloading
- During transport (vehicle movements, windy conditions, change of environment)

Mixed stressors can come from living conditions such as:

- Environmental changes (fluctuations in temperature, lighting schedules or intensity, rains, flooding)
Poultry Disease Handbook for Africa

- Changes in the social order in a flock (new entrants from the market or as gifts)
- Disease, such as parasitism (ecto-, haemo-, and endoparasitism, inapparent infections, and exposure to poisons (household insecticides and herbicides, poisonous plants, and poisonous animals)
- Crowding

Consequences of stress - Immunosuppression: All stimuli that provoke stress will cause immunosuppression. Indigenous poultry are particularly susceptible to stress and this may be reflected in their poor responses to vaccination (Newcastle disease, infectious bursal disease). This has been demonstrated by comparing the responses of commercial birds and indigenous chickens and ducks.

Immunosuppressed birds succumb more easily to both infectious conditions (viral diseases and bacterial diseases) and non-infectious conditions (such as worm infestations) than non-immunosuppressed birds. Some of these birds become carriers of various diseases for healthy birds around them.

To be optimal, any disease control and prevention measures should consider the stressors in family poultry. The raising, transportation, marketing, and movement of birds to and from various sites need to be done in a way that minimizes stress for the birds. Vaccination programs need to be appropriately targeted for scavenging poultry, taking into account their interactions with wild birds, other livestock, and humans, but also considering the difficulty in handling and vaccinating them.

Swollen Head Syndrome

Other names: Facial cellulitis, thick head, Dikkop, SHS, TRT, turkey rhinotracheitis

Clinical signs and lesions: In chicks and poults, there is initial sneezing, followed by reddening and swelling of conjunctiva with attendant foamy exudate. Facial swelling extends over the head and down the jaw and wattles. Adult chickens have mild respiratory disease followed by some birds developing swollen heads. Other signs include disorientation, twisting of the neck, and a significant decrease in egg production (up to 70%).

Differential diagnosis: A disease closely mimicking SHS can be caused by a mixed infection of respiratory viruses (either Newcastle disease virus, avian influenza virus, or infectious bronchitis virus) and specific bacteria (Hemophilus paragallinarum, Pasteurella multocida, Mycoplasma sp.).

Cause, transmission, and epidemiology: The disease is caused by a virus classified as a metapneumovirus. Chickens and turkeys are the known natural hosts. Experimentally, guinea fowl and pheasants are susceptible, but pigeons, ducks, and geese are resistant to the infection. The infection spreads by direct contact with infected birds or indirectly by exposure to infectious material. SHS is present in most countries of the world. Humans can also be infected and will develop flu-like symptoms if exposed to sick or ill birds.

Diagnosis: A definitive diagnosis can be made through the direct identification or isolation and identification of the disease agent in embryonating chicken or turkey eggs, or chicken organ culture from the nasal secretions of clinically ill birds. Serology may also be helpful in confirming exposure when birds have recovered.
T**Treatment:** There is no proven treatment for swollen head syndrome. Antibiotic therapy may be helpful against secondary bacterial infections.

**Prevention:** A commercial vaccine is available but not widely distributed. Prevention is dependent on a comprehensive biosecurity program.

**Recovery:** A premises with infected birds can eliminate the organism through cleaning and sanitation of all facilities and equipment that comes into contact with birds, and by the removal of infectious material, like manure, on the farm. New birds must be introduced only from tested flocks if recovery is to be sustainable.

---

**Ulcerative Enteritis**

**Other names:** Quail disease.

**Clinical signs and lesions:** Quail are the most commonly and most severely affected species. Acute signs are extreme depression and reduced feed consumption. Affected birds sit humped with eyes closed. Other signs include emaciation, watery droppings streaked with urates, and dull, ruffled feathers. Accumulated mortality can reach 50% if the flock is not treated. At necropsy, punctate ulcers are typical and may be visible from the mucosal surface of the gut. Any section of the intestine may be involved. The liver will have circumscribed areas of necrosis and hemorrhage that become depressed over time. The spleen will be enlarged, congested, and hemorrhagic.

**Differential diagnosis:** A differential diagnosis of ulcerative enteritis will include coccidiosis, histomoniasis, and necrotic enteritis. Complicating the differentiation of ulcerative enteritis is the fact that coccidiosis and necrotic enteritis may be predisposing to concurrent infections in affected birds or flocks.

**Cause, transmission, and epidemiology:** The causative agent is the bacterium *Clostridium colinum.* Chickens, turkeys, quail, and other species are occasionally clinically affected. Birds become infected by direct contact with carrier birds, infected droppings, or contaminated pens, feed, and water. Bacteria are passed in the droppings of sick and carrier birds. Infection can be spread mechanically on shoes, feed bags, equipment, and from contamination by rodents and pets.

**Diagnosis:** A diagnosis of ulcerative enteritis is indicated by the presence of typical button ulcers in the intestine with concurrent target lesions in the liver. Confirmation is based on the isolation of the causative agent, *C. colinum.* However, this can be very difficult because the organism is fastidious and difficult to grow in culture. Additionally, cultures may be overgrown by *C. perfringens,* which may also be present. In these cases, a diagnosis will be based on the presence of typical gross lesions.

**Treatment:** Bacitracin and Neomycin can be used singly or in combination. Other antibiotics and drugs such as tetracyclines, penicillin, Lincomycin, and Virginomycin may also be effective. Consult a veterinarian for dose, route, and duration of treatment.

**Prevention:** Ulcerative enteritis is difficult to prevent in quail. When quail have access to their own droppings, this disease commonly occurs. To eradicate, depopulate stock, thoroughly clean and disinfect, and start over with young, clean stock.

**Recovery:** *Clostridium colinum* is a spore-forming organism, and infectious spores will remain in the soil after an outbreak. Over time the spores will be dispersed, resulting in lowered exposure for naïve birds, but
risk will not disappear. Controlling predisposing factors, like immunosuppressive diseases and internal parasites, will make birds more resistant. In highly susceptible species, like quail, preventative medication may be the only means of recovery.

Urolithiasis

Clinical signs and lesions: This is primarily observed in egg production flocks and characterized by severe atrophy of one or both kidneys, distended ureters with uroliths, and varying degrees of renal and visceral gout. It is associated with increased mortality and decreased egg production. Clinical signs include:

- Mortality of up to 50%
- Laying chickens die suddenly, although in good condition and in production
- Reduced muscle mass, small pale combs, and white, pasty exudate on the peri-cloacal feathers
- Atrophied kidneys and dilated ureters, often accompanied by diffuse visceral urate deposits
- Kidney atrophy often more severe in the anterior lobes and usually unilateral, but may be bilateral
- Surviving ipsilateral or contralateral lobes may be enlarged
- Ureters from atrophied lobes are dilated, full of clear mucus, and often contain white irregular concretions or uroliths (compact masses of microcrystalline to fine pleomorphic crystals of calcium/sodium urates, with random substitution of magnesium and potassium for the calcium and sodium, respectively)

Microscopic lesions include:

- Dilated ureter branches and tubules
- Tubular degeneration and loss of tubules
- Cellular casts, urate crystals, and varying degrees of fibrosis
- Minor focal cortical tubular necrosis
- Some eosinophilic globules in glomeruli
- Interstitial infiltration of heterophils and lymphocytes

Differential diagnosis: Increased mortality and decreased egg production can be associated with any number of diseases. Urolithiasis will generally mimic the appearance of, and also can be caused by, management problems like a lack of water or feed. Lesions observed at necropsy will eliminate other conditions.

Cause, transmission, and epidemiology: Urolithiasis is caused by kidney damage resulting in reduced renal mass. It can also be secondary to infectious bronchitis, or due to excess dietary calcium with low phosphorous levels, water deprivation, and some nephrotoxic mycotoxins. Once formed, uroliths cause further renal damage and may cause sudden death by plugging ureters.

Diagnosis: Diagnosis is made at necropsy, by observation of uroliths and damaged or absent kidney lobes. However, a diagnosis of the cause of the renal disease will require more investigation. Feed analysis (for protein and calcium levels) and testing for infectious bronchitis viruses should be standard in cases of urolithiasis.

Treatment: There is no treatment for this disease syndrome.

Prevention: Urolithiasis is prevented by feeding a correctly balanced diet, providing adequate water for chickens, and preventing infectious bronchitis through a combination of vaccination and biosecurity.
Recovery: Affected individuals will not recover, but once the cause of the kidney damage is corrected, then no additional individuals will develop the condition. There is no residual risk to new birds placed on the premises.

Zygomycosis

Other names: mucormycosis and phycomycosis

Clinical signs and lesions: There are both local and systemic types of infections. The clinical syndrome depends on the organ or system infected. There may be incoordination, photophobia, and paralysis. Nodular airsacculitis with involvement of intercostal muscles, multiple nodules in the lungs, ventriculitis, and proventriculitis (ostriches) may be seen. The lesions are pyogranulomatous (with necrotic centers) with numerous multinucleated giant cells evident histologically. Necrosis and angioinvasion with fungal hyphae are near-constant features.

Differential diagnosis: The symptoms of zygomycosis may be non-specific depending on the system affected. Lung infections and systemic fungal infections such as aspergillosis, cryptococcosis, histoplasmosis, and dactyliasis mycobacteriosis should be considered.

Cause, transmission, and epidemiology: The disease is caused by fungi belonging to genera Mucor, Rhizopus, Absidia, Rhizomucor, and Mortierella. They are acquired from environmental sources (soil, manure, and rotting vegetation), and are not contagious.

Diagnosis: Clinical signs of disease, lesions at necropsy, and the epidemiology of the case can be indicative of zygomycosis or other fungal disease. Confirmation of the specific disease agent is by microscopic examination of histological lesions or culture.

Treatment: There is no satisfactory treatment.

Prevention: Good sanitation and hygiene.

Recovery: Cases will re-occur if fungi can grow in the birds’ environment. If, however, the cause of the contamination is corrected and/or the source removed, there is no residual risk to flocks.
REFERENCES

APPENDIX A: Poultry Disease Diagnosis Decision Tree

**Birds < 2 weeks old**

- Depression, mortality
- Nervous signs
- All species

**Ducks only**
- Crops empty, dehydrated.
- Starvation
- Fine tremors
- History of eating moldy feed

**Crops not empty**
- Field unabsorbed yolk
- Hemorrhagic cerebellum
- Starvation

**Birds > 2 weeks old or multiple ages**

- History of exposure to toxin

**Multiple or any species**
- Hemorrhagic lesions in the digestive and respiratory tracts
- Polyserositis

**Ducks only**
- Hemorrhagic in trachea and intestine
- Polyserositis

**Pigeons only**
- Hemorrhagic in trachea and intestine
- Bursal tumor

**History of exposure to a toxin**
- Hemorrhagic lesions in the digestive and respiratory tracts
- Swollen head and sinuses

**Birds are not flaccid**
- Birds are flaccid
- White nodules in atelectasis

**Birds are flaccid**
- Blood or tissue plug in trachea

**History of exposure to a toxin**
- Hemorrhagic lesions in the digestive and respiratory tracts

**Polyposis**
- Hemorrhagic in trachea and intestine

**History of exposure to toxin**
- Hemorrhagic in trachea and intestine
- Polyserositis

**Polyposis**
- Hemorrhagic in trachea and intestine
- Polyserositis
