Abstract

Rural poverty in India is a problem much less of total food availability than of who produces the food and who has the income to buy it. A high priority is therefore to enable the tens of millions of resource-poor farm families to increase their production and improve its stability. The normal 'transfer-of-technology' model for agricultural research has built-in biases which favour resource-rich farmers whose conditions resemble those of research stations. Transfer-of-technology approaches have been modified through on-farm trials and demonstrations but the basic model and approach remain the same. A second emerging model is 'farmer-first-and-last'. This starts and ends with the farm family and the farming system. It begins with holistic and interdisciplinary appraisal of farm families' resources, needs and problems, and continues with on-farm and with-farmer R and D, with scientists, experiment stations and laboratories in a consultancy and referral role. Farmer-first-and-last fits the needs and opportunities of resource-poor farm families better than transfer-of-technology, but there are obstacles to its development and introduction. These can be tackled step-by-step, through combinations of methodological innovation, interdisciplinarity including the social sciences, and provision of suitable resources, rewards and training. Farmer-first-and-last approaches promise a greater contribution from agricultural research to the eradication of rural poverty in India.

The views expressed in this paper are those of the authors and not necessarily those of the Ford Foundation. Comments on the paper will be much appreciated.
The future of our agriculture...depends on the success with which we can help the small and illiterate farmers to take the many small steps which alone can lead to improved methods of farming.

M.S. Swaminathan 1982:33

Resource-poor Farmers: Need and Opportunity

The economic and social benefits from agricultural research can be extremely high. Benefit-cost ratios can exceed those for almost any other form of investment. The dramatic advances in productivity achieved in the green revolution in irrigated wheat in Northwest India in the late 1960s present what is perhaps the internationally best known example. It is true that the preconditions (groundwater, canal water, electrification, infrastructure, land consolidation, potential access to inputs, etc.) were in place to provide an almost ideal environment for the new stiff-and short-strawed HYVs of wheat when they were introduced. But behind the success also lay the imagination of scientists who brought to bear their powerful skills on a perceived need and opportunity. The argument we will develop in this paper is that agricultural scientists today are also faced with a need and an opportunity; that it is different; and that it requires a different solution through new methodology and skills.

The green revolution strategy was evolved in an era when the problem of poverty and hunger was seen largely as a problem of production, of growing more food. Since lack of food could lead to undernutrition and starvation, it seemed logical to attribute undernutrition and starvation, when they were found, to food shortages. If enough food could be produced, hunger would be vanquished. Given the diagnosis, the strategy was well conceived. It concentrated on those farmers and those areas with the greatest apparent potential for producing more food. If it favoured the better-off farmers and the better-endowed areas, this was justified since they presented the conditions in which the new high-yielding technologies generated on research stations could most readily be adopted. The Intensive Agricultural District Programme, thought out on these lines, was targeted to districts with good irrigation and good infrastructure. It was a policy of consciously betting on the strong, and its successes in Northwest India are well-known.
In the past decade there have been significant shifts in understanding of poverty and hunger and in priorities. In terms of national economy, total food production remains very important. In 1983 India imported about 8 million tons of foodgrains, following five years of stagnation in total foodgrain production. Although performance in 1983-4 is better (estimated at 142 million tons), there remains a need to achieve much higher and more stable production, with an aggregate gross demand for foodgrains estimated at 225 million tons by the year 2000. Vast rainfed dryland areas have yet to register significant progress, and they constitute some 75 per cent of the cropped area of the country, contributing about 42 per cent of total food production. Attention has shifted towards giving higher priority to raising production on these rainfed lands.

Supporting this shift, it is also recognised that increased food production alone is not sufficient to overcome rural poverty. In the new understanding, most elegantly and eloquently demonstrated by Amartya Sen (1981, 1982), famines and family food shortages result much less from shortages of food supply, and much more from lack of means to grow it or of income to buy it. This is especially so in India where as a result of public information, political commitment, and good organisation, and in contrast with China, food supply shortages are not permitted to occur on any scale. In the words of M.S. Swaminathan: 'Famines in India are often famines of work rather than of food, since when work can be had and paid for, food is always forthcoming' (1983:461 2). For overcoming rural poverty, much more important than total food produced is the question of who produces it and who can obtain it. This directs attention towards the needs and interests of those who were largely by-passed by the green revolution technologies, the tens of millions of farm families who are resource-poor.

A resource-poor farm family is defined as one whose resources of land, water, labour and capital do not currently permit a decent and secure family livelihood. Such families include many though not all of those with marginal (0-1 ha) and small (1-2 ha) farm holdings and many others with more than 2 ha but whose land is infertile, vulnerable to floods or erosion, or subject to low and unreliable rainfall. The abbreviation RPF refers to resource-poor farm or resource-poor farmer according to context.

Three major reasons can be given for orienting more agricultural research to serve the interests and fit the conditions of RPF families, so defined:

i. **Social Justice.** RPF families include many of the poorest and most vulnerable people. Their numbers are very large. At least three-quarters of operational holdings in India are less than 2 ha (Kalra 1981) and they must number over 60 million. However, some farmers with less than 2 ha are not RPFs, and some with more are. If arbitrarily these are taken as cancelling out, we would have 60 million families, or some 300 million people, in this category. Substantial breakthroughs in adoptable technology for RPF families might thus have a widespread impact on poverty.

ii. **Production.** The social justice argument is enough in itself. But in addition, RPFs comprise well over one quarter, perhaps between one third and one half, of the area of land under operational holdings, much of it rainfed. (Holdings under 2 ha constitute about one quarter). Increases in the productivity of this land would therefore have a substantial impact on total production. The production potential on RPFs will almost always be less than on resource-rich farms, but past relative neglect and failures promise that the potential that exists for increased production is still largely unexploited. Moreover, there is potential for reducing risks for RPFs, which is very important for them, besides enabling them to increase production.

iii. **Employment.** Improved farming systems for RPFs should generate productive work round more of the year. High proportions of additional income among the poor, such as RPF families, are also spent on locally produced consumption and capital goods, and these purchases in turn generate employment for others.

The question is, then, how agricultural research can be oriented efficiently to serve the needs and conditions of RPF families. To seek answers to that question, we will examine two contrasting models for agricultural research.

---

1. Many caveats deserve to be made concerning this figure. Even if the true figure is less, however, the magnitude would remain very large.
Model A: Transfer-of-Technology

The transfer-of-technology model is deeply embedded in the thinking of many professions and disciplines around the world. It is part of the structure of centralised knowledge in which power, prestige and professional skills are concentrated in well-informed 'cores' or centres. These cores or centres generate new technology which then spreads (or does not spread) to the peripheries. Highly trained civil, mechanical and agricultural engineers, medical scientists, agronomists and others develop technologies in laboratories, workshops and experiment stations, and then attempt to transfer them to would-be clients. This approach has had immense successes in industry and agriculture with resource-rich clients. In agricultural engineering, the development of mechanisation through combine harvesters, tractors and threshers, and in seed-breeding the development of high-yielding technological packages, have often enabled the resource-rich to increase their productivity and profitability. But the approach has also had severe shortcomings for would-be clients who are resource-poor.

In most agricultural sciences, the "cores" or centres in which research is conducted are experiment stations, glasshouses and laboratories, supported by back-up services, with provision for controlled conditions, with excellent access to inputs, and without significant cost or labour constraints. Scientists in the experiment stations, glasshouses and laboratories generate or test new technologies and then pass them over to extension services to transmit to farmers. In political and scientific meetings, speeches about the vital importance of the transfer of technology are a predictable feature. Physical, biological and social scientists alike have held the transfer of technology from scientists to farmers to be a central concern. The model has until recently been part of the valued and respected structure of thinking of almost all professionals concerned with agricultural research.

In practice, as is now only too well known, the transfer of technology often presents intractable problems with resource-poor farmers. When RPFs did not adopt 'good' new technology, both social scientists and agricultural scientists at first attributed this to ignorance. The large-scale social science research in India in the 1960s on 'diffusion of innovations' assumed that the technologies were good and appropriate. A major premiss was that if small

1. For this perspective and argument presented in more detail, please see Chambers 1983:4-10, 75-82 and 168-169.
farmers did not adopt them, it was because they did not know about them, or did not know enough about them. The prescription that followed was for more and better extension, as the Extension Directorates of the Agricultural Universities testify. The standard phrase, so often repeated, that 'We must educate the farmer', exactly reflects the underlying pattern of thought. 'We' have the relevant knowledge. Ignorant farmers do not have it. We must teach the ignorant farmers.

But there is now much evidence and understanding that when RPFs do not adopt technology it is often not from ignorance but because the technology does not fit their needs and their physical, social and economic conditions. Technologies, whether biological or physical, bear the imprint of the conditions in which they are generated. They are then adoptable in similar conditions, but often not adoptable where conditions differ. As it happens, many conditions on research experiment stations and in laboratories are close to those of resource-rich farmers, and sharply different from those of resource-poor farmers. The contrasts are presented in Tables 1 and 2.

When these contrasts are taken together, it is easier to understand why so much new technology is adopted by the resource-rich and not by the resource-poor. Most non-adoption by RPF families can be explained by the inappropriateness to their needs and resources of the technology to be transferred.

The transfer-of-technology model remains, however, not only dominant but nearly universal. Before examining the alternative model, it will be useful to see why this is so. Four main reasons can be suggested.
1. **the proven power of the model**

The transfer-of-technology model has demonstrated strengths, especially in plant-breeding and varietal development. Much basic research requires controlled conditions and precise and difficult measurements which are best achieved in laboratories and on research stations. The Transfer-of-Technology model has contributed to great and conspicuous increases in food production, most notably in the Green Revolution.

2. **international transfer of the model**

The transfer-of-technology model has itself been transferred and reinforced internationally. The approaches of the Land Grant Colleges in the United States have been transferred to the Agricultural Universities of India. In the United States the model generated technology for the resource-rich. Many of the resource-poor sold out and were able to migrate to the booming cities. In effect, the high-input, capital-intensive and extensive monocropping generated on research stations 'colonised' the farm environment and displaced smaller-scale more subsistence farming systems and families for whom there were other niches in the economy. Scientists from the rich, temperate North have thus little reason to question the model. For them it has worked and it continues to work. They do not have to face the problem of tens of millions of resource-poor subsistence or near-subsistence farmers for whom it does not fit, in an environment in which migration of the poor to the cities is not a feasible large-scale 'solution'.

3. **scientists' rewards and motivations**

There are strong professional reasons why agricultural scientists should follow the transfer-of-technology model. At the international and national level, there is the prestige attributed to "high" technology, seed breeding, and expensive and sophisticated equipment and methods of research. Norman Borlaug's Nobel Prize was for applications of this model. Then there is personal convenience in working in office and laboratory, and on a research experiment station rather than on-farm or with-farmer. Further, for gaining professional recognition and for minimising risk of not gaining it through failed experiments, in-laboratory and on-station work under controlled environment, is to be preferred. The environments of resource poor farmers are very complex. There are too many stresses with too many interactions. Moreover the research methodology for such environments is not well established.
It is safer for professional advancement and recognition not to share the farmers' risks. And at a deeper psychological level, the values and thinking which place the scientist on a pedestal as a pandit, generating new knowledge and dispensing it to the surrounding masses, is personally gratifying.

4. **Interlocking biases against the resource-poor**

Scientists' rewards and motivations interlock with other well-known biases of professional behaviour, contact and perception towards those rural people who are better off to the neglect of those who are poorer. Scientists are often urban-based. Their rural visits have spatial biases - urban, tarmac, and roadside, and towards large villages and village centres - concentrating attention where the better-off tend to be located. Other biases concern contact with those with higher status, more influence, greater wealth, and better education - in short, the resource-rich, to the neglect of those with lower status, less influence, less wealth, and less education - in short, the resource-poor. Scientists meet adopters more than non-adopters. It is progressive, resource-rich farmers on whose land demonstrations are most often laid out, and who provide hospitality and cups of tea for visiting officials. Then there are also biases of modernity and capital-intensity: it is the tractor, the pump, the thresher, the inorganic fertiliser and other purchased inputs, which attract attention. In their own backgrounds, too, many scientists come from relatively rich families, often urban, and few have known life in a resource-poor farm family. They are also 'season-proofed' in that they do not personally experience, as a farmer does, the vagaries and difficulties of dependence on the monsoon. Nor does their income depend on uncertain agriculture: their pay cheques are regular and monthly, not seasonal and variable. When these and other factors are taken into account, it is more than understandable that agricultural scientists have difficulty appreciating RPF conditions and that they do not doubt that the transfer-of-technology model is appropriate for their work. They have good reason to embrace it and little reason to question it: they rarely meet or interact with resource-poor farmers; their research is heavily weighted towards the conditions of the resource-rich; and it is from the resource-rich who adopt much more than the resource-poor who do not adopt that they get most of their feedback on the value of their technology.

1. For more detailed description of these and other biases, please see Chambers 1983:7-25 and 171-179.
In the light of disappointing experience with transfer of technology to resource-poor farmers, many modifications have been made to the model. No summary description can do justice to these, but some at least deserve to be mentioned to indicate the scale and scope of the effort that has been made, and to set subsequent discussion in perspective.

The transfer-of-technology model and modifications to it are well exemplified in major agricultural research programmes (see e.g. Research Highlights, 1981, Indian Council of Agricultural Research, Krishi Bhavan, New Delhi 110001). For example, as is well known, research on major food crops is conducted through All India Coordinated Crop Improvement Projects located in Agricultural Universities and Central Institutes. The experiments are primarily carried out at Experiment Stations, with emphasis on varietal improvement, production technology and plant protection. Under different All India Coordinated Soil and Water Management Projects, special technologies are developed for specific problem areas, such as reclamation technology, dryland technology and so on. Operational Research Projects have been implemented for specific problem areas such as the management of alkali soils, composite fish culture, control of cotton pests, dryland agriculture for semi-arid red soils (Sanghi 1982), and so on. For small, marginal and landless agricultural labourers, the Lab-to-Land programme was started. The major thrust was the introduction of new technologies for diversification of labour use and the introduction of supplementary sources of income such as apiculture, aquaculture, sericulture, and home crafts. A number of Transfer of Technology Centres have been created in Agricultural Universities, Central Institutes and other Government organisations and voluntary agencies. In backward areas the Krishi Vigyan Kendras have been established for training farmers in new technologies.

These programmes present progressive modifications of the model and attempts to offset its biases. There has been increasing emphasis on on-farm trials and demonstrations. The All India Coordinated Project on National Demonstrations has been organised and implemented. The attention directed to problem environments focuses on farmers who are often by definition resource-poor. The lab-to-land programme is explicitly directed towards them. The establishment of Krishi Vigyan Kendras in backward areas for training farmers in new technology follow the same pattern of a thrust towards the resource-poor.
It is, however, perhaps fair to say that the outcomes in terms of adoption of new technology by RPFs has been disappointing. The old explanation of 'ignorance' on the part of RPFs has been partly superseded by attempts to understand farmers' conditions and constraints. Technology generated by research is tested on farmers' fields under farmers' management conditions. The large yield gaps between crop yields obtained in National Demonstrations are compared with the much lower yields actually obtained by farmers. Yield gap analysis is then undertaken to identify the relative significance of different constraints which face farmers. This is a long step forward from attributing non-adoption mainly to ignorance.

But the basic model remains the same. Priorities are set by scientists relying on their professional understanding and criteria. Research is conducted in central locations and then extended outwards, tested, and modified. There has, it is true, been increasing emphasis on feedback from the field. There are farmers' melas at Agricultural Universities and Institutes. The T and V system encourages some closer contact between agricultural research scientists and farmers. But throughout, the farmers from whom there is feedback tend to be precisely those best placed to benefit from the technology generated. It is scarcely to be expected that many resource-poor farmers, illiterate, and powerless as they so often are, will be able to demand the services of agricultural scientists, or will go to melas and speak up about their problems. What feedback comes is mainly from the progressive and better-off farmers, and does not throw into question the basic structure of research activity. Resource-poor farmers whose needs and resources the technology does not fit are precisely those who do not come and speak up, who are not sought out, and from whom scientists are least able or inclined to learn.

Our conclusion is that for all its manifest power to achieve results on experiment stations and on the fields of resource-rich farmers, the transfer-of-technology model of agricultural research does not encourage scientists to learn from resource-poor farmers. Even in its modifications it has not shown itself well-suited to generating technology which they can and will adopt.
Model B: Farmer-First-and-Last

The farmer-first-and-last model entails fundamental reversals of learning and location. These, we argue, are necessary if research and the technology it generates are better to fit the needs and conditions of RPF families.

Farmer-first-and-last differs from transfer-of-technology in starting not with scientists and their perceptions and priorities, but with RPF families and theirs. It begins with a systematic process of scientists learning from and understanding RPF families, their resources, needs and problems. The main locus of research and learning is the resource-poor farm rather than the research station and the laboratory. Research problems and priorities are identified by the needs and opportunities of the farm family rather than by the professional preferences of the scientist. The research station and the laboratory have a referral and consultancy role, secondary to and serving the RPF family. The criterion of excellence is not the rigour of on-station or in-laboratory research, or yields in research station or resource-rich farmer conditions, but the more rigorous test of whether new practices spread among the resource-poor.

The sharp distinction which we see between transfer-of-technology and farmer-first-and-last has been blurred by some of the meanings given to 'farming systems' and 'farming systems research'. Farming systems research sometimes means 'upstream' research, in which elements of a farming system are evolved and investigated on an experiment station. This is a transfer-of-technology approach. In contrast, there is 'downstream' farming systems research which starts and ends with farmers, beginning with systematic attempts to understand the farm family and farming system. This is a farmer-first-and-last approach.

Four Prototypes and Variants

Farmer-first-and-last approaches are not entirely new, but neither have they been fully explored, fitted together, and evolved. Several variants have been described in the literature which we have examined. They are still being developed and so can be considered prototypes. They include CIMMYT's approach to planning technologies appropriate to farmers (Byerlee, Collinson et al. 1980; Collinson 1981); the Sondeo method of rapid appraisal (Hildebrand 1981); ICRAF's D and D (diagnosis and design) for agro-forestry (Lundgren and Raintree 1983; 11

1. For useful reviews see Gilbert et al. 1980 and Biggs 1983.
Raintree and Young 1983); and the farmer-back-to-farmer methodology of CIP (Rhoades and Booth 1982). These will be briefly described and then compared.

i. **CIMMYT.** The CIMMYT approach emphasises the farmer as the primary client of agricultural research, and farmer circumstances as the basis for planning research. It pays much attention to the methods whereby farmer circumstances are identified. Farmers are grouped into 'recommendation domains' - groups of farmers for whom more or less the same recommendations can be made. There is a focus on a target crop. Rapid appraisals are conducted by an agronomist and an economist working together. Background information is assembled. An exploratory survey is carried out, using a checklist of farmer circumstances, classified as:

- natural circumstances
- external socio-economic circumstances of markets and institutions
- farmers' goals and resources
- relevant features of the total farming system
- description of production practices for the target crop

(Byerlee and Collinson 1980:13). This is followed by a formal verification survey with a questionnaire (which, however, may well be superfluous after a well-conducted exploratory survey). Analysis of data and prescreening of technological components then lead to the identification of "best bets" and on-farm experiments with these.

ii. **Sondeo.** The Sondeo approach developed by Hildebrand (1981) in Guatemala is strongest in its technique used for the creative combination of disciplines in rapid appraisal to generate new technology. A zone with homogeneous farming practices is identified, in which there are to be farm trials of technologies which are as yet not identified. A team leader and ten team members - five of them agronomists or animal scientists, and five from socio-economics - conduct a very rapid appraisal. They work in pairs - one agronomist or animal scientist with one socio-economist - changing partners each day for five days. They visit the area, and interview farmers and others, attempting to understand the farming system and to identify feasible and suitable improvements, and all brainstorm together each
evening. At the end of the five days, many three-cornered discussions between farmers, social scientists and agricultural scientists have contributed to proposals for improved farm practices. A report is written under pressure and provides proposed innovations for the Technology Testing Team which then works in the area with on-farm and with-farmer trials.

iii. ICRAF's D and D. ICRAF's diagnosis and design (D and D) methodology sets out to identify promising candidate agro-forestry technologies. Major emphasis is placed on the farm household management unit and the satisfaction of its needs. The methodology also seeks to address a broader range of production and conservation objectives than most farming systems research, emphasising productivity, sustainability and adoptability. A minimal team includes one or more representatives of agricultural science (general agronomy, horticulture, and livestock sciences), forestry (in the broadest sense), social science (sociology/anthropology, human geography and economics), and natural sciences concerned with land resource survey (ecology, soils science, climatology). The application of D and D procedures by a multidisciplinary team usually entails about two weeks to carry out the diagnostic survey, analyze the results and develop appropriate design concepts for agroforestry interventions to improve the existing land use system. There is a four stage procedure - prediagnostic, diagnostic, design, and follow-up planning. The D and D procedures are seen as part of a continuing learning process and may be repeated.

iv. CIP's farmer-back-to-farmer. The original farmer-back-to-farmer research (Rhoades and Booth 1982) was conducted on potato storage in Peru by scientists and an anthropologist. The anthropologist learnt about farm families' objectives and their knowledge of and problems with potato storage, and acted as a link between them and the scientists, bringing the scientists into direct learning contact with the farmers. There were four stages - establishing a common definition of the problem; interdisciplinary team research seeking a solution; testing and adaptation of the proposed technology on-farm, with farmers contributing ideas; and "farmer evaluation: the last judgement". The result was an improved and adoptable technology which met farmers' objectives, used materials to which they had access, fitted in with their traditional house design, and above all was adopted by them. A key element was changes of perception and priority on the part of the scientists. For example, what appeared losses to scientists were not necessarily losses to farmers, who had uses for shrivelled or spoiled potatoes. One scientist reflected later:
"I was not totally convinced of the anthropologists' argument, although he certainly made me think about what I was doing. We (biological scientists) hadn't even really talked to a farmer about the problems we were working on. We were doing research about a problem from a distance, not research to solve a problem. When I finally went with him to visit farmers I could see he was right, but only partially."

(Rhoades and Booth 1982:129)

The Prototypes Analysed

These four, and other, farmer-first-and-last approaches emphasise:

- rapid and cost-effective appraisal
- holistic farming systems analysis, including the farm household and its needs
- learning from farmers
- inter-disciplinarity with genuine dialogue
- on-farm and with-farmer R and D
- a consultancy and referral role for scientists and experiment stations
- evaluation by farmers' adoption

In comparing the four approaches - CIMMYT, Sondeo, ICRAF D and D, and CIP farmer-back-to-farmer - each has its special emphases. These can be presented as follows:
### Strongest Emphases in Different Farmer-First-and-Last Methodologies

The absence of any x's for 'strongest emphases' against 'resource-poor farm family focus' reflects a lack of explicit priority to RPF families. All four approaches include the definition of a reasonably homogeneous clientele group, often described as a 'recommendation domain'. This may include many resource-poor farmers, but in general the smaller and poorer farmers do not appear to have been deliberately sought out in these approaches. It seems quite likely that many of the farmers interviewed and worked with will have been among the somewhat better off. These farmers may be subject to the same physical constraints of soils, and rainfall, but may differ from RPFs in their cash resources, access to inputs and credit, scale of operation, storage facilities, need for subsistence, and so on. Small and marginal farmers face their own specific problems, in resource-poor zones as elsewhere, and these four approaches do not in themselves guarantee that their conditions and needs will be catered for. A deliberate and difficult effort has to be made to include them.
From these examples, the three major components of a farmer-first-and-last model can be identified as:

i. starting with a diagnostic procedure, learning from farmers

ii. generating technology on-farm and with-farmer

iii. evaluation of technology by its adoption or non-adoption by farmers

i. diagnosis. The point about diagnosis preceding the determination of research priorities has been forcefully made by Lundgren and Raintree (1983:43) in justifying ICRAF’s D and D methodology:

'It is a cardinal rule in the medical profession that diagnosis should precede treatment. In practice there are exceptions to this rule, of course, but it would be unthinkable for doctors ever simply to ignore the diagnostic process altogether, and prescribe treatment without due regard for the specific nature of the patient's illness. We would hardly tolerate a haphazard, hit-or-miss approach to treatment from professions dealing with human pathologies. How strange then that we have come to accept such an approach when it comes to treating pathologies arising from man's use of the earth. Is this not in fact what happens when a traditional agricultural or forestry research station develops a new technology and recommends it for dissemination? In how many instances is the treatment preceded by adequate diagnosis of the actual and perceived problems which confront the majority of land-users in the recommendation domain? The answer of many researchers, that they 'already know what the problems are' without having to bother with the complications of a formal diagnostic procedure, is analogous to a doctor's making either the patently absurd assumption that all patients are the same, or his claiming arrogantly that a well-trained practitioner is able to treat patients without recourse to an examination.'
There is now a substantial literature on rapid appraisals but much scope for inventiveness remains. The Art of the Informal Agricultural Survey (Rhoades 1982) is one key element. What has formerly been regarded as something anyone can do is now seen as a set of skills which can and should be learnt. Problems are posed where multi-disciplinary teams cannot be assembled, and methods and training are required for agricultural scientists who have perforce to conduct such appraisals on their own.

ii. R and D on-farm and with-farmer. There are tests and experiments which require strictly controlled conditions and precise measurements which are most feasible on research stations, in glasshouses, and in laboratories. But if the R and D process is confined to such conditions, the constraints, resources, complexities and stresses of the farm level are automatically eliminated from the generation and screening of technology. Characteristics of the evolving technology will reflect the objectives and criteria of scientists, the resources of the research station, and the controlled environment. Features of the evolving technology which might better fit farmers' needs and conditions may often not be included. Small farmers also have a widespread capacity to experiment and innovate themselves as Brammer (1980) has vividly illustrated from Bangladesh, and can contribute as professional colleagues to the R and D process.

The example of potato storage technology in Peru (Rhoades and Booth 1982) illustrates this point. At first scientists worked on potato storage generally, but farmers defined their problem more precisely as the sprouting of stored seed potatoes. When this became the priority problem, scientists worked on-station on the known scientific principle that natural diffused light reduces sprout growth and generally improves seed quality. At the same time ways of applying the principle were worked out with farmers and in their houses, using materials available to farmers and fitting in with traditional house architecture. Improvements in storage were achieved and the new technology was adopted and spread, with farmers making further adaptations.

1. See Chambers 1981 for a list of some sources.
Had the locus of application of the principle not been the farmers' houses, the classical problems of trying to transfer a research station technology might well have arisen, and scientists and extension staff might to this day be struggling to persuade farmers to adopt a technology appropriate for the research station but not for farmers' conditions. As it was, the joint collaboration of farm family and scientist in the farm environment ensured that adoptability was built into the technology development process itself.

Another example is of maize on-farm research at Pantnagar (Agrawal 1983). Hybrid maize with a high yield potential was not accepted by the farmers. With maize 'on-farm' research trials a direct and effective dialogue between researchers and farmers was established. One reason for non-adoption that emerged was that the soil and climatic conditions of Pantnagar did not represent those of farmers. Another was that farmers' varieties had better adaptability and grain quality. With a change in breeding priorities resulting from the on-farm work and the dialogue, new varieties could be developed which were acceptable to the farmers.

iii. evaluation by adoption. The final element in farmer-first-and-last is evaluation by resource-poor farmers themselves. The test of a new technology is not yield on a research station or on the land of a resource-rich farmer, but whether resource-poor farmers actually adopt it. For this to occur, it noted, the technology must usually entail direct satisfaction of the perceived needs of the family, low risk, and little or no reliance on purchased inputs. These, we argue, are much more likely features of the technology when its generation has been preceded and determined by diagnosis and by on-farm and with-farmer R and D, than with the transfer-of-technology model.

Reversals of Explanation, Learning and Location

Farmer-first-and-last entails reversals of explanation, learning and location.

The reversal of explanation concerns non-adoption. There can be seen to be three levels or stages of explanation of non-adoption of new technology by farmers. These are presented in Table 3.
Table 3. Non-adoption: Changes In Explanation And Prescription

<table>

</tr>
</tbody>
</table>

The major reversal is that explanation of non-adoption shifts from deficiencies of the farmer and the farm level, to deficiencies in the technology and in the technology-generating process.

The reversal of learning requires that scientists start by systematically learning from farmers, with transfer of technology from farmer to scientist as a basic and continuous process.

The reversal in location requires that R and D take place on-farm and with-farmer, with research stations and laboratories in a referral and consultancy role.

The nature of these reversals are illustrated in Table 4.

Each model has its major problem. That of the first is the transfer of inappropriate technology to resource-poor farmers. That of the second is the transfer of inappropriate scientists to resource-poor conditions. In the first case the technology, and in the second the scientists, bear the deep imprint of resource-rich conditions. For farmer-first-and-last to be feasible requires changes among scientists. These entail a sort of psychological 'flip', seeing the world the other way round, as the RPF family does; or as psychologists sometimes say, 'taking hold of the other end of the stick'. 
The mental set of farmer-first-and-last is thus radically different from that of transfer-of-technology. It has been well stated by Rhoades and Booth in their own farmer-back-to-farmer approach:

'The basic philosophy upon which the model is based holds that successful agricultural research and development must begin and end with the farmer. Applied agricultural research cannot begin in isolation on an experimental station or with a planning committee out of touch with farm conditions. In practice, this means obtaining information about, and achieving an understanding of, the Farmer's perception of the problem and finally to accept the Farmer's evaluation of the solution...' (Rhoades and Booth 1982:132. Their emphases)

Practical Implications

obstacles to adoption by scientists

To adopt and adapt the farmer-first-and-last approach on any scale, stressing resource-poor farmers, would be difficult. Even those few methodologies which have been developed, like the four quoted, are not familiar in India. The Transfer-of-Technology model is very stable, with inbuilt buffering against change. Systematic learning from farmers is not a part of professional training. Multi-disciplinary teams are difficult to muster, and truly interdisciplinary collaboration is not easy. Social scientists are either not available, or liable to have narrow concerns and orientation - costs of cultivation, partial budgetting, social cost benefit analysis and so on - which fall short of an understanding of farming systems. Then resources (vehicles, allowances, village-level staff, stores for inputs, etc.) for extended fieldwork in appraisals and work on-farm and with-farmer are often not easily available. Work on research stations or on larger farmers' fields is more easily and conveniently controlled, inspected, measured and shown to others. For some scientists, it may quite simply be uncongenial to spend time with farmers, let alone with those who are resource-poor. On-station work may also more readily and predictably lead to publishable papers which advance a scientist's career and lead in a conventional manner to national and international recognition. Professional values take modern scientific knowledge as superior, advanced and sophisticated, and little appreciate or respect the knowledge of farm families. Transfer-of-technology can, in sum, be convenient and gratifying, allowing scientists to conduct their elite
and clean work in controlled quasi-laboratory conditions, and passing to others - extension staff and social scientists - the messy and lower status work of transferring the technology, educating the farmer, and overcoming whatever constraints to diffusion and adoption there may be.

five thrusts

Innovations with parts or variants of farmer-first-and-last have doubtless already been developed in various places in India, and others may be planned, as with the ICRAF D and D methodology in the All-India Coordinated Research Programme for Agro-forestry. Any attempt to develop and introduce the farmer-first-and-last model on a wider scale can be seen to require five complementary thrusts:

i. methodological innovation. Eclectic use of elements of methods already developed elsewhere need to be combined with innovation in and for Indian conditions, with special stress on resource-poor areas and farm families. By analogy with the collection of genetic material, methodological material needs to be collected from different environments. Access is needed to relevant experience in other countries, as well as from within India, and some of this is already available in journals, although some may have only limited distribution in India.

ii. interdisciplinarity. Full interdisciplinarity entails collaboration between farmers, technical scientists and social scientists. In practice, the social scientists are often either not available or not properly equipped for this sort of work. Few institutions

---

1. In this field there is a problem in the international diffusion of innovations. One difficulty is the high cost of international journals combined with what may be conservative disciplinary policies in ordering them. To take one example, some of the most significant methodological papers (e.g. Collinson 1981, Hildebrand 1981, Rhoades and Booth 1982) have been published in Agricultural Administration. Per annum this costs UK pounds 126.60 (about Rs.1,900) for 12 issues. It is available at the National Academy of Agricultural Research Management but it is taken by only three Agricultural Universities - GKVVK University of Agricultural Sciences, Bangalore (2 copies), the Tamil Nadu Agricultural University, and the Assam Agricultural University.
can muster a combination of, say, agricultural sciences, farming-systems-oriented agricultural economics, and sociology and social anthropology. Even if they could, social scientists are often not properly equipped for this sort of work. The best feasible may often be that farmers and agricultural scientists together do the best they can.

ii. **resources.** Rapid appraisals require resources for travel and work out of station, as does on-farm and with-farmer R and D. Vehicles and funds for travel do not guarantee such travel if scientists and others do not wish to undertake it; and vehicles and funds are not always absolutely essential. Nevertheless, to be realistic, their availability will in practical terms often be a precondition for effective farmer-first-and-last work.

iv. **rewards.** Apart from exceptional individuals, scientists would need to feel that they would be rewarded for behaviour which was both inconvenient and liable to be less productive in professional terms, for example publications. One measure would be to encourage self-critical writing about experience with the farmer-first-and-last approach and methodologies such as rapid appraisals. Another would be to recognise through promotions and rewards exceptional work in this field, putting it on a par with high-status genetic and microbiological work. An annual competition might be held with an award for the best farmer-first-and-last R and D.

v. **training.** How to learn from farmers, like how to manage an organisation, is a set of skills that most people think they have; but like management, learning from farmers has specialised techniques and can be taught and learnt (see for example Rhoades 1982). Techniques for diagnostic survey, analysis and design can also be taught. Attitude changes are more difficult, but simulation games like Green Revolution (Chapman 1983) and Monsoon (Staley 1981) can help, and further simulation games in which scientists play resource-poor farmers could be devised. The National Institute of Agricultural Research Management with its mix of important disciplines and experience with techniques of management training, would seem well placed to develop a training programme emphasising a farming systems approach and farmer-first-and-last.
Conclusion

Among scientists, changes of model or shifts of paradigms are sometimes described as revolutions. They entail seeing the familiar in an entirely new way and they are usually resisted by professional establishments. However inadequately, we have tried to sketch how farmer-first-and-last represents a new and different model for the conduct of agricultural research. But it does not fit current staffing, resources, orientation and training. If, however, our argument is correct that it is a more cost-effective way of generating technology adoptable by resource-poor farm families, then the question is not whether but how it can be developed and introduced. The professional incentives for far-seeing scientists should be strong. The model challenges them to develop new methodologies. In the longer term there is a promise of professional recognition and rewards for those who pioneer. And above all there should be the profound satisfaction of developing technologies which enable many resource-poor farm families to secure a better livelihood from agriculture.

Appendix I

Rice production in Eastern India - an example

A GOI/IRRI production oriented survey on rice in Eastern India (1977) observed that yields had not increased in kharif rice for two decades. The average yields of rice had remained more or less unchanged at about 0.93 q. per ha., despite a very large increase in yield potential made available with new HYVs. All attempts to transfer the HYV technology had failed to make an impact in kharif. The major problem appeared to be water control. HYVs cannot withstand prolonged water-logging and submergence in low lands or under intermittent flash floods, whereas the local tall varieties possess tolerance to submergence.

Under pressure to increase rice production rapidly for growing demand of ever increasing population, research has been directed towards high potential areas which hold the prospect of most rapid payoff - flat lands with assured irrigation, uplands favoured by rain, low lands with low level of flooding i.e. in those areas where physiography, climate, institutional and infrastructural conditions are most favourable. The disadvantaged areas have been neglected.

The low coverage under HYV is obviously due to fact that existing HYV cannot give reliable performance in these disadvantaged areas and the farmer is reluctant to invest in costly fertilizers and other agricultural inputs. High yielding varieties do very poorly under late transplanting conditions due to delayed onset of monsoon and are affected by diseases and pests. What is needed is to introduce highly stable varieties instead of high yielding varieties and appropriate farming practices that will give reliability and security of profit to the farmer.
