## Forevord

This is the second in a series of field reports on the work done by the CILSS Regional Woodstoves Technical Coordinator and collaborators. These are not polished, final reports but rather represent an attempt to get research resulrs into the field quickly in order to aid other ongoing work and to stimulate debate.

Thanks again go to numerous people and organizations. First, thanks go to the National Center for Rural Artisan Training (CNPAR), Ouagadougou for use of their courtyard in Cissin to perform these tests. We would like to express special thanks to Mamadou Traore of the Handicapped Artisans Center, Ouagadougou, and Frederic Yerbanga, Guilougon, for their construction of the fired clay stove prototypes; to Mr. Norbert of the Cissin Meral Center for his construction of the metal stoves; and to Fred lottenroth, President of the $2 Z$ Corporation, for use of the $Z$ Ztove. Thanks also go to the Wuod-Burning Stove Group at Eindhoven for their pioneering work on shielded fires. Without the excellent support by these individuals and groups, the work presented here would not have been possible.

## I. INTRODUCTION AND SUMMARY

In this study, a wide variety of one-pot chimneyless stoves were tested a few times each in order to provide some direction for future efforts to develop optimal stove designs. Such an effort has recently gotten underway at the Voitaic Institute of Energy (IVE).

As in the first field report, From October 1982, all the stoves tested here were the one-pot chimneyless type. As discussed in the October report, these stoves have a number of advantages, as well as a few potential disadvantages, over the massive stoves now being disseminated throughout West Africa and many other parts of the world. These are briefly discussed below.

EFFICIENCY: The fired clay and metal stoves presented here show nigher thermal efficiency than any known massive stove. Massive stoves with chimneys typically show Percents of Heat Utilized (PHUs) of 14 to $21 \%$, and up to $25 \%$ for chimneyless models (report to be published). There are several reasons for the low efficiency of mas ive stoves:

- Surface for heat exchange. The one-pot stoves tested here provide for the hot gases to escape up around the pot, effectively increasing the surface area for heat exchange. Massive stoves with chimneys provide little surface for heat exchange to any of the pots because of the necessity to close off the stoves to prevent the escape of smoke into the room. Spherical pots aggravate this problem. The use of brittle materials such as banco (or sand and clay) can also reduce the exposed surface area, since providing a sufficiently strong support for the pot often requires constructing a very thick top plate, covering even more of the pot than could be exposed to the hot gases. Chimneyless masiive stoves perform better than those with chimneys, since the second pot (or first, in the one-pot model) has more heat exchange area with the hot gases.
- Combustion. Combustion is better in the stoves tested here than in massive stoves generally because a grate is provided that uniformly aerates the eatire firebed.
- Draft. The draft in a massive stove is uncontrolled and usually far too large. At the door, air pulled into the stove can hit the first pot and cool it. Because of the large channel below the fiist pot and the more or less stagnant air just below the top plate around it, convective heat transfer to this pot is small. To control the draft and improve heat transfer to the second pot, a baffle is usually placed directly below it to force the not gases onto the second pot. However, the perfcrmance of the stove is fairly sensitive to the construction of this baffle and, at best, the thermal efficiercy of the second pot is low. Tests show second pot efficiencies of roughly a Eourth to a third that of the first pot. Because of this the second pot often does not heat well enough to actually cook, and the heat recuperated is of little use other than for preheating cooking or bathing water, or keeping food marm.

A righ efficiency stove with a chimney is possible but requires a complete redesign of both the pot and the stove (report to be published).

HEAT RECUPERATION: Because of their very low mass, these lightweight stoves do not absorb a significant amount of heat that might later be used to heat water after the fire is out; massive stoves do. However, tests (report to be published) indicate that the total amount of recuperable heat in a massive stove is only 1 to $2 \%$ of the total generated by the fire and is thus negligible. Therefore, it is more efficient to always use a high efficiency stove such as the lightweight ones discussed below than to use a low efficiency massive stove and attempt to recuperate heat from it after cooking.

COST: The fired clay and metal stoves tested here can be produced for less than 1,000 CFA (US $\$ 1=350 \mathrm{CFA}$ ) Eor a single small-to mediumsized pot. It is likely that the cost of fired clay stoves can be reduced considerably. In Mali, a traditional one-pot, chimneyless fired clay stove costs the equivalent of $150-250$ CFA. By comparison, massive cement stoves for two pots cost roughly 5,000 CFA.

PRODUCTION: The fired clay stoves similar to those presented here have been produced at a rate of 12 to 15 per day, and rates of 20 per day per porter may be possible. In a production test of the metal stoves (Sepp), rates of 60 per day by a team of three teenagers were achieved with no difficulty. By comparison, a mason cannot construct more than two cement stoves or one banco stove per day. In adition, facilities that could be used for the production of fired clay or metal stoves are already in place throughout much of the Sahel, and artisans are already trained to work with these types of materials. This may dramatically reduce the difficulty of establishing production facilities and logistics support, as well as reduce the magnitude of the artisan training programs necessary. Stove dissemination programs would thus be simply a matter of adding an additional product to the existing product lir:Es of local artisans.

PORTABILITY: Portable stoves may be desirable for both the urban poor, who move frequently and who can't afford to buy a massive, fixed stove that they can't carry with them, and for people who prefer to cook in different areas according to the weather.

STABILITY: The portable stoves are not as stable as massive scoves; this may be a drawback.

LIFETIME: All the materials used have potential drawbacks in terms of lifetime. Fired clay resists heat and water well but is brittle. Cement resists water and physical shocks well but breaks down when exposed to heat. Banco tends ro crack somewhat when exposed to a fire, and to melt in the rain. Metal is strong and shock resistant but tends to corrode (depending on the type) wt:en exposed to high temperatures in the presence of water vapor, such as occurs when burning wet wood.

HEALTH: The chimneyless stoves presented here do not provide for the evacuation of smoke (part of the reason for their high efficiency) and thus do not provide the health benefits that a stove rith a chimney provides.

SOCIAL ACCEPTABILITY: Many portable metal stoves and massive stoves are already in use in West Africa.

There were several significant tests results. First, despite the high thermal conductivity of their metal walls, the metal stoves performed quite well. With very simple design changes from the traditional West African "malgache" metal stove, significant improvements in thermal performance are possible. Simply adding a grate to this "malgache" stove increased its average PHU from $18 \%$ to $24 \%$. Further, raising the walls around the pot and leaving only a narrow gap ( 1 cm ) between the pot and stove walls for the smoke to escape further increased the PHU to $29 \%$. It is hoped that rather simple adjustments in existing metal artisan stoves can mean important savings in wood use. As the skills, materials (in cities), and facilities are already in place, dissemination of metal stoves, in principle, may become much easier.

Second, the importance of this pot shielding was strongly empliasized by comparing the performance of the simple metal cylinder stove with a grate to the $Z$ Ztove (Hottenroth). The $Z$ Ztove has optimized combustion, but bescause it does not provide pot shielding to force the hot gases against the entire pot surface, it does not perform any better than the simple cylinder. Presumably, though not yet tested, adding a pot shield to this stove would improve its performance.

Third, following the October report further tests were done on the effect of secondary air and grate height. It was found that the addition of secondary air had no observable effect on the performarce of the fired clay stoves tested, but that a smaller grate to pot distance did improve heat transfer somewhat.

Fourth, several double wall and preheated primary air arrangements were tried. Though the double wall arrangement improved performance somewhat over the one wall metal cylinder, it is not likely to be sufficiently economizally justified. The preheating arrangement showed no statistically significant improvement over the simple double wall. Further testing needs to be done before any definitive statement is made.

## II. DESIGN OF THE STOVES TESTED

A r.raditional three-stone "stove," five one-pot chimneyless fired clay stoves, and fourteen one-pot chimneyless metal stoves were tested. The three-stone and fired clay stoves, as well as the pots, were described in the October report and are summarized on the foliowing pages for convenience. Detailed descriptions of the metal stoves are also provided, as is a discussion of the parameters tested with each variation.

It must be noted in examining the stove and fot designs that the values given for the dimensions are not very precise. For the fired clay stoves in particular, the edges are rounded, making difficult a determination of where a certain feature starts or stops; wall thicknesses vary; and, firing warps the form of the stove so that even forms shaped on a potter's wheel do not remain constant (i.e., have a constant diameter.) Some of these imprecisions are noted on the following pages. In addition, none of the drawings are precisely to scale; they are only illustrative.

POTS: The pots used were made of aluminum. Their dimensions are given in Table I below, and a sketch is provided in Figure $1 B$. The two $\}$ pots were used interchangeably in all stoves, except stove $F$ where the small difference in dimensions prevented the heavier 非3b pot from entering the stove opening and seating properly. Only with stove $B$ were the 102 and if $^{2}$ pots used.

TABLE I
SUMMARY OF STOVE DLMENSIONS

## Stove

|  | 非2 | 133 | \#3b | $\ddagger 4$ |
| :---: | :---: | :---: | :---: | :---: |
| Top diameter (cms) | 22.0 | 24.5 | 24.5 | 27.5 |
| Maximum diameter | 24.5 | 26.5 | 27.0 | 30.5 |
| Total height | 18.0 | 19.0 | 19.0 | 21.0 |
| Heighc from bottom to maximum diameter | 8.0 | 10.0 | 10.0 | 10.0 |
| Weight (kgs) | 0.93 | 1.28 | 1.58 | 1.81 |
| Volume (liters) | 5.5 | 7.8 | 7.9 | 11.5 |

STOVE A: A sketch of "stove" A, the traditional three-stone fire, is shown in Figure lA (traced from De Lepeleire). Three rocks are placed on a concrete $s l a b$ to support the pot. The distance from the slab to the pot bottom is kept at roughly 10 cm . The diameter of the firebed can be as large as 20 cm but is typicaily 10 to 15 cm .

STOVES B, $C, D, E$, and F: These are all fired clay stoves and are described in more detail in the Octcber report. All of the stoves are made entirely of fired clay, including the grate. They have a single wall and an open (unclosable) door for wood entry. There is no preheating of primary or secondary air. Pot supforts, five in all, consist of three equally spaced strips of fired clay 7.5 cm thick by 4 to 5 cm long, and 2.5 cm wide. Sketches of these stoves are found in Figure l. A summary of their dimensions is given in Table II.

STOVES $H, K, L, M$, and $N:$ These are cylindrical and are made of 1 mm sheet steel (and, in some cases, iron rebar for pot supports). Stove $Z Z$ is a combination of metal with fiberglass insulation.

STOVE H: This is a traditional metal "malgache" stove purchased in a local market. It consists of a metal cylinder with a solid hottom, a large door, and three metal tabs on the top rim of the cyliader extending inwards and downwards at a small angle to support the pot. The tabs are 6 cm wide by 6 cm long, with the corners well rounded and a slight taper going out.

STOVE K: This stove has a grate, a wall that rises up around the pot, and a triangular pot support made of rebar as shown in figure $1 E$.

STOVE L: This is nearly identical to the traditional "malgache" stove (Stove H) except that it has a smaller door and a grate punched into the normally solid bottom. For air to enter the grate it was necessary to place this stove on three supports to raise it off the ground.

STOVE M: This is a double wall stove with a closable door. The outer wall is simply a cylinder with a sol d d bottom and a sliding door. The inner wali has the rounded and tapered tabs for pot sunports as in Stove $H$, a grate that is raised up off the solid bottom of the exterior wall, and vents in its walls to let air in below its grate. When used with the door open, the space between the walls was closed at the top with a piece of cloth to create an insulating deat air space. When used with the door clos?d, the space between the walls was left open for air to enter at the top, descend, and preheat from contact with the hot inner wall before entering the combustion chamber.

STOVES $N$ : These are all simple metal cylinders with the same size door ( 10 cm high by 12 cm wide, of which the lower 3.5 cm is below the grate) and vents (two vents, 8 cm wide and 3.5 cm high) to let air in below the grate. The vents are on opposite sides of the stove and at right angles to the door. The grate (with 200 holes 0.8 cm in diameter) itself is removable, as is ihe pot support ( 12 cm from grate to pot bottom). The pot support is made of two pieces of rebar bent into

upside down "W's," contoured to the shape of the pot and welded together at thair point of contact in the center, with additional struts attached between their legs for strength. For larger diameter shields a metal ring is placed on the grate to block air entry between the grate and the stove wall. As the same grate and pot support are always used in these tests, the parameters of firebed aeration and pot height above the firebed do not affect tha results. In this way different heights and diameters of pot shields can be tested to determine the effect on efficiency and the sensitivity of the efficiency to variarions in these parameters.

STOVE ZZ : The $Z$ Ztove is produced by the $Z Z$ Corporation. It consists of an outer shell of sheet metal 17 cm wide by 15 cm deep by 24 cm bigh. Within is a layer of high temperature insulation around a cylindrical combustion chamber 10 cm in diameter and 15 cm deep from grate to stove top. There are three openings into the stove: a 3.5 cm diameter hole whose center is 4.5 cm from the top of the stove for wood entry (this limits the size of wood to less than 3.5 cm diameter by 9 cm long); a slot, 5.5 cm wide by 1 cm high, 17 cm from the top of the stove, with a sliding door for secondary air to enter; and a slot, 21 cm from the top of the stove, 12 cm wide and 1.5 cm high, for primary air and for a tray to catch the cinders that fall from the grate. The sliding tray is 11.5 cm wide by 14 cm long by 1.5 cm deep. Secondary air is preheated and enters the combustion chamber through 36 holes 0.6 cm in diameter, each spaced 3 cin apart in spiral strips from the level of the grate to within 4 cm of the top of the stove. The pot rests on a spacer about 3 cm above the top of the stove. There is no provision for pot shielding.

A number of variations in the basic stoves listed above were tried to determine the effect of different parameters on stove performance. A summary of these variations is given in Table IV, using the same notation as on the data sheets.

For the fired clay stoves these variations give data on the effect of side vents ( $B$ and $C$ ), the effect of a grate ( $D$ ), the effect of the grate height ( $E$ and $F$ ), the effect of primary and secondary air ( $D, E$, and $F$ ), and the effect of the height of the stove wall around the pot (E vs. F).

Stoves H, K, and $L$ show the effect on the traditional metal stove of adding a grate and raising the wall of the stove around the pot. Stove $M$ crudely shows the effect of a door, double wall, and preheating the primary and secondary air. The $N$ stoves show the effect of various heights and diameters of stove walls around the pot. Stove $Z Z$ shows the effect of optimized combustion without the advantages of pot shielding.

## III. TEST XETHODOLOGY

The methodology used, described in detail in the October report, generally followed the draft procedure developed by the "Worting group metering on a woodstove field test standard, Marseille, 12 - 14 May 1982" and by Dr. Timothy $S$. Wood. Tests were completed November December 1982. A sample Lest sheet follows the testing prucedure described below. On the sample test sheet letters are filled in that correspond to the columin headings in the raw data in section VI, Test Results.

The testing procedure listed here is identical to that used in the October report.

1. The stove and area around it is swept clean of ashes and other debris. The stove is felt co make sure it is cool. Because of the stcver' very low thermal mass, cooling generally takes no more than 30 minutes.
2. Weather conditions, particuiarly wind, are noted.
3. Wood is chopped into pieces roughly 3 cm by 3 cm by 20 to 30 cm long, along with a number of very small pieces to start the fire. All wood, including kindling, is then weighed on scales accurate to 10 g over 5 kg and set to the side of the stove. A smaller amount is withdrawn from this pile, separately weighed, and used to start the fire. Any wood put into the fire is weighed and recorded separately, in addition to the overali wood weight. This provides a check that wood is not misplaced during the test
4. The pot to be used is weighed and its weight recorded. Approximate$1 y 3 \mathrm{~kg}$ of water are added to the pot, and the total weight of pot plus water recorded.

The same pots and same balance tray are used each time, and their weights are known. Nevertheless, they are carefully weighed each time so that, first of all, changes in the balance performance can be quickly spotted, and secondly, so that analysis of all the readings will provide a rough error analysis and estimate of the balance's precision.
5. The wood is then arranged in the stove, a small ( 1 ml or so) amount of kerosene added to the wood, and the wood set on fire. While the Eire becomes established, (a minute or so) the water temperature is taken. Once the fire is burning well, the pot is placed on the stove, and a stopwatcll is started.
6. The temperature of the water is recorded every five minutes until the water begins to boil. The wood is pushed in or added (after weighing ard recording) in order to maintain a reasonably stead; but not excessively large, fire. Different testers vary dramatically in their attitude as to what constitutes "a reasonably steady
but not excessively large fire." (In this study, variation was reduced by attempting to ensure that a tester tested each stove the same number of times.) Observations such as the color and extent of smoke, the effect of the wind on the stove, or flames shooting out the door or stove top are recorded.
7. As soon as the water starts to boil, the fianes are blown out; the wood left in the stove is weighed and recorded; the tolal amount of wood remaining is weighed and recorded; and the po! is weighed and recorded. The emount of charcosl in the stove is neither weighed nor estimated until the end of the second part of the test. Ir those cases where the pot refuses to come to a boil, i.e., where it stays at a temperature of $90^{\circ} \mathrm{C}$ for more than 15 minutes, the first part of the test is ended as though it had been successfully sempleted.
8. No lids of any sort are used during any part of the test. The pots remain completely uncorered throughout.
9. After all wood and pot weights are taken and recorded, a small amount of wood is again taken from the larger pile, weighed, and added to the stove. The fire is relit, the water temperature recorded, the pot of water returned to the stove, and the timing begun again.
10. Temperature is again recorded every five minutes. The fire is maintained at a steady level to keep the water tomperature above $90^{\circ} \mathrm{C}$ but below a vigorous boil. Again, lids are not used on the pots.
11. After 60 minutes the fire is again blown out, the weight of the wood remaining in the stove recorded, the total remaining wood weight recorded, the pot weight recorded, and the weight of the charcoal remaining after the test recorded.

It should be noted that this procedure does not provide a good resolution of the high power and low power abilities of the stove, because as pot lids are not uses chere is a high rate of heat loss from the pot. In order to keep temperatures close to boiling under these circumstances, the tester is obliged, even during the second part of the test--the "iow power phase"--to maintain a fairly high power level. It is not clear in practice, however, how useful a true low power measurement is. Combustion can be maintained at nearly any power level with dry wood. In testing a low power level, one may be testing more the patience of the tester to cut the wood into small pieces and feed it into the stove than a real performance parameter of the stove itself.

## SAMPLE LABORATORY TEST DATA SHEET

## SIMMERING TEST:

## IV. CALCULATING THE PERCENT hEAT UTILIZED

The procedure used for calculating the percent heat utilized (PHU) was identical to that in the October report. The formula used was

$$
\mathrm{PHU}=\frac{4.184(\text { water })(\text { temp })+2,260(\text { evap })}{18,000(\text { wood })-29,000(\text { charcoal })}
$$

where "water" is the initial weight of the water, "temp" is the temperature change of the water, "evap" is the mass of water evaporated, "wood" is the mass of the wood burned, and "charcoal" is the mass of charcoal remaining at the end of the test.

All weights are given in kilograns and all temperatures are given in centigrade. Note that the thermal capacity (weight $x$ specific heat) of aluminum is ignored as it is small. The error due to this factor is discussed in greater detail below.

As noted previously, this calculation contains some implicit assumptions.

It assumes, with little error, that the latent heat of evaporation of water is $2,260 \mathrm{~J} / \mathrm{gm}$, and that the specific heat of water is $4.184 \mathrm{~J} / \mathrm{gm}$ C.

Much less justifiable are the assumptions that the heat values of wood and charcoal are $18,000 \mathrm{~J} / \mathrm{gm}$ and $29,000 \mathrm{~J} / \mathrm{gm}$ respectively. This was not verified during the course of these tests.

In the data and anrlysis that follow, three different PHUs are calculated: the PHU to bring the water to a boil; the PHU of simmering the water for one hour; and the average PHU for these two parts.

The PHU for bringing the water to $a$ boil was calculated using the equation:

$$
\mathrm{PHU}_{1}=\frac{4.184(\mathrm{D}-\mathrm{C})(\mathrm{H}-\mathrm{G})+2,260(\mathrm{D}-\mathrm{K})}{18,000(\mathrm{~F}-\mathrm{J})-14,500(\mathrm{~N}-\mathrm{E})}
$$

where the letters indicate the data listed in the sample test sheet (see previous section) and in the columns of raw data that follow. Note that the calorific value of the charcoal remaining at the end of the test is divided equally between the first and second phases. The values for $\mathrm{PHU}_{1}$ are listed as a percentage under column "El" in the List of Calculated Results, Table VII.

The PHU for simmering the water for an hour is calculated similarly. In this case, the equation used is:

$$
\mathrm{PHU}_{2}=\frac{4.184(\mathrm{~K}-\mathrm{C})(\mathrm{H}-\mathrm{L})+2,260(\mathrm{~K}-\mathrm{O})}{18,000(\mathrm{~J}-\mathrm{M})-14,500(\mathrm{~N}-\mathrm{E})}
$$

The values for $\mathrm{PHU}_{2}$ are listed as a percentage in column E2, Table VII, List of Calculated Results.

The average PHU, listed as a percentage in column EA, Table VII, was calculated using the equation:

$$
\mathrm{PHU}_{\mathrm{A}}=\frac{4 \cdot 184(\mathrm{D}-\mathrm{C})(\mathrm{H}-\mathrm{G})+2,260(\mathrm{D}-0)}{18,000(\mathrm{~F}-\mathrm{M})-29,000(\mathrm{~N}-\mathrm{E})}
$$

Although the charcoal was weighed only once and its weight divided between the boiling and simmering stages of the test in calculating the PHU, it is likely that the charcoal is established mostly during the first stage and a steady state condition reached during the second stage. Dividing it equally between the two stages will then tend to understate the first PHU figure and overstate the second figure.

The fire power during the first and second stages was also calculated and is listed in Table VII as "Pl" and "P2," in units of kilowatts. The equations used to calculate these values were:

$$
\begin{aligned}
& P 1=\frac{18,000(F-J)-14,500(\mathrm{~N}-\mathrm{E})}{60(\mathrm{I})} \\
& P 2=\frac{18,000(\mathrm{~J}-\mathrm{M})-14,500(\mathrm{~N}-\mathrm{E})}{3,600}
\end{aligned}
$$

Greater detail on all these points is given in the October report.

## V. ERROR ANALYSIS

A complete error analysis was made in the October report and will not be repeated here. In summary, it was shown that for a balance accurate to 10 grams and a stove with a PHU of $27 \%$, intrinsic measurement errors gave an error of roughly $\pm 1.4 \%$. Thus, extreme attention must be given to the accuracy of the balance and, further, to ensure that the balance does not drift during the testing series. In the work done here a set of standard OHAUS weights was used to check the balance's accuracy periodically.

In addition to the problems with balance precision, it was noted above that the weight of the aluminum pot itself was not included in the PHU calculation. When the same pot is always used this obviously does not pose problems. However, in this series of tests, pot sizes from \#2 to \#4 wero used with stove B.

Beginning with a representative test for stove $B$, 非214, we can calculate the amount of energy used to heat the different aluminum pots, and compare that to the average PHU as calculated.

Acding a term for heating the mass of aluminum from the starting to the boiling temperature for the different sized pors we find:

| Pot | Mass | PHU |
| :--- | :--- | :--- |
| -- | -- | $27.1 \%$ |
| \#2 | 0.93 kg | 27.5 |
| \#3a | 1.28 | 27.7 |
| \#3b | 1.58 | 27.8 |
| \#4 | 1.81 | 27.9 |

where we have used $0.896 \mathrm{~J} / \mathrm{gm}-\mathrm{C}$ for the specific heat of aluminum (water has $\mathrm{C}=4.184 \mathrm{~J} / \mathrm{gm}-\mathrm{C}$ ).

It must be noted that using the values as given in the List of Data (Table VI) gives a PHU of $26.95 \%$ instead of $27.1 \%$. The difference is due to using a data printout format that rounds off the values listed to fit them into the column width. In this case the value for the initial wood weight was rounded from 2.205 kg to 2.21 kg , which causes the above discrepancy. The calculated values of PHU, etc., listed in the tables use the original values, with no rounding off.

The values found above show that the error due to not including the aluminum weight of the pot itself is sinall and can be ignored for the tests presented here.

In addition to the above internal errors, there were several problems with the test methodology.

WIND: As previously discussed, the wind was observed to be an important facior affecting the tests. A wall was placed around each test site to reduce the wind's effect. Each wall was 80 cm high and in the shape of a "U" 70 cm wide and 110 cm deep. The open end of the $U$ faced a three story building approximately 2 m away, reducing wind from that direction to essentially zero. Nevertheless, crosswinds were observed to disturb the stoves, and some data taken on the most windy days have been removed from consideration.

WCOD MOISTURE CONTENT: The wood moisture content was not highly variable during this series of tests since all wood was pre-dried before use, as discussed in the October report. Drying was done by placing the wood in clear polyethylene tubes 30 cm in diameter and 200 cm long for about one week before use. These tubes full of wood were left in the sun and tilted at an angle of approximately 10 degrees, to both heat the wood and provide a small air current through the thermosyphon effect to remove the moisture from the tube. Internal temperatures at midday were about $10^{\circ} \mathrm{C}$ above ambient. Flaps at the end of the tubes were left hanging to prevent the rain from entering. The moisture content of air-ditied wood was later measured and found to be about $6 \%$. Although unknown, it is likely that the moisture content of the wood used for these tests was less than that.

A number of problems were observed in individual tests and are lister in Table $V$ on the following page.

## LIST OF TESTS WITH PROBLEMS

| Test Number | Problem |
| :---: | :---: |
| 134 | Problems with fire, wood lost dur |
| 145 | Problems with fire |
| 154 | Missing weight of pot and water at intermediate step |
| 157 | Missing weight of pot and water at intermediate step |
| 170 | Stopped after the first half due to darkness |
| 189 | Door was opened and closed throughout the test to observe the effect |
| 193 | Heavy winds |
| 196 | Test with covered pot |
| 199B | Test with covered pot |
| 200 | Test with covered pot |
| 204 | Test with covered pot |
| 205 | Test with covered pot |
| 206 | Test with covered pot |
| 207 | Test with covered pot |
| 221 | Heavy winds |
| 224 | Heavy winds |
| 241 | Problems with fire |
| 242 | Missing data |
| 261 | Missing data |
| 267 | Heavy winds |
| 275-289 | Tests were done at a new testing site to give new testers some experience using chese stoves |

It is ciear from looking at the variation in PHUs between tests that there remain several uncontrolled variables.

None of the above data is included in the stove PHU averages. In the summary in Table VIII they are listed in parentheses.

* The values listed in Table IX give:
average $\pm$ standard deviation (number of tests)
Lines connecting adjacent tests indicate which tests do not have a statistically significant difference. This was determined only between adjacent stove variations for the same stove, by using the
t-test (Brownlee).

## VIII. CONCLUSIONS

In analyzing the preceding data, the following can be noted.
A three-stone fire has significantly better performance (at least when using an alumitum pot) than the typical vaiues of $;-5 \%$ or $5-8 \%$ giver for it in most stove literature. Further testing at field sites verifies this; results will be presented elsewhere.

Stove $B$ performance is relatively independent of the size of pot used.
Stoves $E$ and $F$ show that having a higher wall around the pot and a grate closer to the pot improve performance but do not show any significant difference between having and not having secondary air. An analysis of variance on these factors is being done and will be presented elsewhere.

Stoves $H, K$, and $L$ snow that, $f i r s t$, the traditional improved stove $H$ does perform significantly better than an open fire. However, by adding a grate (stove L.), and by raising the wall up around the pot (stove K), significant improvements in the performance of the traditional stove can be made. These improvements can be made at little cost and with the same artisans, production facilities, and distribution networks as presently used. Further, as will be shown elsewhere, such a stove (stove $K$ ), performs significaully better than massive stoves with chimneys.

Stove $M$ showed no significant difference between having the door open (anc dead air space between the walls) and the door closed (and air descending between the walls to preheat before entering the combustion chamber). Further, the improvement over a single-wall stove such as stove $K$ was mall and likely would not be economical. More work will be done on this.

Stoves crudely showed the effect on stove efficiency of the stove diameter and height relative to the pot. Though the data presented are far too brief, they indicate a rapid reduction in stove performance with increasing diamecer and/or declining height. Further work is being done on this to determine in greater detail the sensitivity of the stove performance to these parameters.

Stove $z Z$ showed that it is not enough to have optimized combustion; it is also necessary to force the heat into the pot by using a shield that rises up around the pot, as in stoves $K$ and $N$. This can be seen very clearly in heat balance analyses such as those done at Eindhoven, which indicate that the losses due to incomplete combustion are typically less than $10 \%$ of the total heat output of the fire, while stove body and flue gas losses combined are typically close to $70 \%$.

In terms of large-scale dissemination, stove $Z 2$ has several other problems. It is more expensive and more difficult to fabricate than a simple metal cylinder with a grate, and it requires that wood be
chopped intc small pieces to enter the stove. Cutting wood into small pieces will require chipping machines. Small wood also requires that the person using the stove pay considerably more attention to feeding the fire than is now necessary, All these points pose serious obstacles to putting such stoves out into the field.

Finally, it is interesting to note for stove $F$ that the tests with the pot covered show no significant difference in performance compared to the tests with the pot open. This is expected since the parameter being cested is the heat transfer to the pot from the hot gases. As the pot temperature is at boiling with or without the lid, the heat transfer, determined by the temperature difference between the hot gases and che pot, remains the same. Only at low power, and at temperatures below boiling where the evaporation of water from the pot changes dramatically with the use of a lid, will there be a significant difference.
